8 Autoimmune thyroiditis (Hashimoto's disease) is the most common cause of spontaneous hypothyroidism in the adult.[119] Patients may present either with goitrous thyroid gland enlargement and mild hypothyroidism or with thyroid gland atrophy and more severe thyroid hormone deficiency. Both forms of autoimmune thyroiditis probably result from cell- and antibody-mediated thyroid injury. The bulk of evidence suggests that the presence of specific defects in suppressor T-lymphocyte function leads to the survival of a randomly mutating clone of helper T lymphocytes, which are directed against normally occurring antigens on the thyroid membrane. Once these T lymphocytes interact with thyroid membrane antigen, B lymphocytes are stimulated to produce thyroid antibodies.[120]

Antithyroid peroxidase (antimicrosomal) antibodies are present in virtually all patients with Hashimoto's thyroiditis and appear to be directed against the enzyme thyroid peroxidase.[121] These antibodies are capable of fixing complement and inducing cytotoxic changes in thyroid cells. Antibodies that are capable of stimulating thyroid growth through interaction with the TSH receptor may occasionally be found particularly in goitrous hypothyroidism; conversely, antibodies that inhibit the trophic effects of TSH are present in the atrophic type.

Hypothalamic disease

Iatrogenic Hypothyroidism

Iatrogenic hypothyroidism follows exposure to excessive amounts of radiation (radioiodine or external radiation) or surgery. Hypothyroidism occurs within 3 months to a year after ^{131}I therapy in most patients treated for Graves's disease. Thereafter it occurs at a rate of approximately 2.5% each year. External radiation therapy to the region of the thyroid using doses of greater than 2,500 cGy for therapy of neck carcinoma also causes hypothyroidism. This effect is dose dependent, and more than 50% of patients who receive more than 4,000 cGy to the thyroid bed develop hypothyroidism. Total thyroidectomy causes hypothyroidism within 1 month.

Other Causes of Primary Hypothyroidism

Iodine deficiency, enzymatic defects within the thyroid gland, thyroid hypoplasia, and maternal ingestion of goitrogens during fetal development may cause cretinism. Early recognition and treatment of the resultant thyroid hormone deficiency is essential for optimal mental development.[122,123] Large-scale neonatal screening programs in North America, Europe, Japan, and Australia are now in place.[124] The frequency of congenital hypothyroidism in North America and Europe is 1 per 3,500 to 4,000 live births. In the United States, there are racial differences in the incidence of congenital hypothyroidism, with whites being affected seven times as frequently as blacks.

In the adult, hypothyroidism may rarely be caused by iodine deficiency and goitrogens. Rarely, iodine ingestion in the form of expectorants can lead to hypothyroidism. In sensitive persons (particularly those with autoimmune thyroiditis), the iodide blocks the synthesis of thyroid hormone, leading to an increased secretion of TSH and thyroid enlargement. Thus, both iodine excess and iodine deficiency can cause decreased secretion of thyroid hormone.

Causes of Secondary Hypothyroidism

Pituitary Disease TSH is required for normal thyroid secretion. Thyroid atrophy and decreased thyroid secretion follow pituitary failure. Pituitary insufficiency may be caused by destruction of

TABLE 84-8 Thyroid Preparations Used in the Treatment of Hypothyroidism

Drug/Dosage Form	Content	Relative Dose	Comments/Equivalency
Thyroid USP Armour Thyroid (T_4:T_3 ratio) 9.5 mcg:2.25 mcg, 19 mcg:4.5 mcg, 38 mcg:9 mcg, 57 mcg:13.5 mcg, 76 mcg:18 mcg, 114 mcg:27 mcg, 152 mcg:36 mcg,190 mcg:45 mcg tablets	Desiccated beef or pork thyroid gland	1 grain (equivalent to 60–100 mcg of T_4)	Unpredictable hormonal stability; inexpensive generic brands may not be bioequivalent.
Thyroglobulin Proloid 32 mg, 65 mg, 100 mg, 130 mg, 200 mg tablets	Partially purified pork thyroglobuin	1 grain	Standardized biologically to give T_4: T_3 ratio of 2.5:1; more expensive than thyroid extract; no clinical advantage.
Levothyroxine Synthroid, Levothroid, Levoxyl, Thyro-tabs, Unithroid and other generics 25, 50, 75, 88, 100, 112, 125, 137, 150, 175, 200, 300 mcg tablets; 200 and 500 mcg per vial injection	Synthetic T_4	50–60 mcg	Stable; predictable potency; generics are bioequivalent; when switching from natural thyroid to L- thyroxine, lower dose by 1/2 grain; variable absorption between products; half-life = 7 days, so daily dosing; considered to be drug of choice.
Liothyronine Cytomel 5, 25, and 50 mcg tablets	Synthetic T_3	15–37.5 mcg	Uniform absorption, rapid onset; half-life = 1.5 days, monitor TSH assays
Liotrix Thyrolar 1/4-, 1/2-, 1-, 2-, and 3-strength tablets	Synthetic T_4: T_3 in 4:1 ratio	50–60 mcg T_4 and 12.5–15 mcg T_3	Stable; predictable; expensive; lacks therapeutic rationale because T_4 is converted to T_3 peripherally.

TSH, thyroid-stimulating hormone.

thyrotrophs by either functioning or nonfunctioning pituitary tumors, surgical therapy, external pituitary radiation, postpartum pituitary necrosis (Sheehan syndrome), trauma, and infiltrative processes of the pituitary such as metastatic tumors, tuberculosis, histiocytosis, and autoimmune mechanisms.[125,126] In all these situations, TSH deficiency most often occurs in association with other pituitary hormone deficiencies. The identification of secondary hypothyroidism due to bexarotene use has led to recognition of the role of rexinoids, and retinoids to cause dysregulation of TSH production.[25,127]

For most hypothyroid patients with pituitary disease, serum TSH concentrations are generally low or normal. A serum TSH concentration in the normal range is clearly inappropriate if the patient's T_4 is low.

Note that pituitary enlargement in hypothyroidism does not invariably indicate the presence of a primary pituitary tumor. Pituitary enlargement is seen for patients with severe primary hypothyroidism due to compensatory hyperplasia and hypertrophy of the thyrotrophs.[128] With thyroid hormone replacement therapy, serum TSH concentrations decline, indicating that the TSH secretion is not autonomous, and the pituitary resumes a more normal configuration. These patients are easily separated from patients with primary pituitary failure by measuring a TSH level.

Hypothalamic Hypothyroidism TRH deficiency also causes a rare form of central hypothyroidism. In both adults and children it may occur as a result of cranial irradiation, trauma, infiltrative diseases, or neoplastic diseases.

TREATMENT

HYPOTHYROIDISM

PHARMACOLOGIC THERAPY

Desired Outcomes

The goals of therapy are to restore normal thyroid hormone concentrations in tissue, provide symptomatic relief, prevent neurologic deficits in newborns and children, and reverse the biochemical abnormalities of hypothyroidism.

General Approach

9 Any of the commercially available thyroid preparations accomplish this goal (Table 84–8); however, levothyroxine (l-thyroxine, T4) is considered to be drug of choice for treatment of hypothyroidism. Other commercially available thyroid preparations can be obtained but are not considered preferred therapy. Available thyroid preparations are synthetic (levothyroxine, liothyronine, and liotrix) or natural (i.e. desiccated thyroid and TG) in origin. The availability of sensitive and specific assays for total and free hormone levels as well as TSH now allow definitive dose titration to allow adequate replacement without inadvertent overdose. The response of TSH to TRH had been advocated for use by some for "fine tuning" thyroid replacement, but this is not necessary if the third generation chemiluminometric assays for TSH, which have detection limits of about 0.01 milli-international units/L, are used. Moreover, TRH is no longer commercially available. Minimum clinical guidelines for the treatment of hypothyroidism have been published by the American Thyroid Association[59] and the American Association of Clinical Endocrinologists.[129]

Synthetic Thyroid Hormones

Levothyroxine (T_4; l-thyroxine) is the drug of choice for thyroid replacement and suppressive therapy because it is chemically stable, relatively inexpensive, and free of antigenicity and has uniform potency. Whereas T_3 and not T_4 is the biologically more active form of thyroid hormone, levothyroxine administration results in a pool of thyroid hormone that is readily and consistently converted to T_3; in this regard levothyroxine may be thought of as a prohormone. The ability of levothyroxine to achieve normal T_3 concentrations was illustrated in a study of recently athyreotic patients in whom levothyroxine monotherapy produced similar T_3 levels to those documented prior to the patient's thyroidectomy.[130] The half-life of levothyroxine is approximately 7 days. This long half-life is responsible for a stable pool of prohormone and the need for only once daily dosing with levothyroxine. Older studies with levothyroxine suggested that bioavailability was low and erratic; however, this product has been reformulated, and the average bioavailability is now approximately 80%.[131–133] Different levothyroxine preparations contain different excipients such as dyes and fillers. The bioavailability of Synthroid, Levoxine, and

generic levothyroxine preparations were compared in a blinded, randomized, four-way crossover trial.[134] The study was sponsored by the manufacturers of Synthroid, who have challenged the authors' conclusions that the levothyroxine preparations are bioequivalent and should be interchangeable for the majority of patients. However, because the relationship between T_4 concentration and TSH is not linear, very small changes in T_4 concentration can lead to substantial changes in TSH, which is a more accurate reflection of hormone replacement status. Currently, the Food and Drug Administration mandates that levothyroxine bioequivalency testing be done for normal volunteers (600 mcg in the fasted state) and three baseline free thyroxine concentrations be used to correct for endogenous T_4 production. Bioequivalency is based on the area under the curve (AUC) and maximum concentration (Cmax) of T_4 out to 48 hours. Approximately 70% of the AUC is derived from endogenous production. TSH is not considered, and it is now very clear that T_4 is too insensitive as a measure of bioequivalency.[135,136] To avoid over- and undertreatment, once a product is selected, therapeutic interchange should be discouraged. Currently, there are several levothyroxine products available, and a number of permutations for interchange are available considering that there are AB1, AB2, AB3, and AB4 products available since no reference listed drug is mandated in bioequivalency testing.

The time to maximal absorption of levothyroxine is about 2 hours and this should be considered when T_4 concentrations is determined. Ingestion of levothyroxine with food can impair its absorption.[137] This can potentially affect the TSH concentration achieved if levothyroxine timing with respect to food is varied.[138] Mucosal diseases such as sprue, diabetic diarrhea, and ileal bypass surgery can also reduce absorption. Cholestyramine, calcium carbonate, sucralfate, aluminum hydroxide,[139] ferrous sulfate,[140] soybean formula,[141] dietary fiber supplements,[142] and espresso coffee[143] may also impair the absorption of levothyroxine from the gastrointestinal tract. Acid suppression with histamine blockers and proton pump inhibitors may also reduce levothyroxine absorption.[144] Drugs that increase nondeiodinative T_4 clearance include rifampin, carbamazepine, and possibly phenytoin. Selenium deficiency and amiodarone may block the conversion of T_4 to T_3.

Liothyronine (T_3) is chemically pure with known potency and has a shorter half-life of 1.5 days. Although it can be used diagnostically in the T_3-suppression test, T_3 has some clinical disadvantages, including a higher incidence of cardiac adverse effects, higher cost, and difficulty in monitoring with conventional laboratory tests. Liotrix is a combination of synthetic T_4 and T_3 in a 4:1 ratio that attempts to mimic natural hormonal secretion. It is chemically stable and pure and has a predictable potency. The major limitations to this product are high cost and lack of therapeutic rationale, because most T_3 is peripherally converted from T_4. In addition, the ratio of T_4:T_3 is much higher than the 14:1 molar ratio produced by the thyroid gland in humans.

Trials comparing levothyroxine alone to a combination of levothyroxine plus partial replacement with liothyronine (triiodothyronine) have generally shown that combinations of T_4 + T_3 are no better than T_4 alone.[145,146] Over 10 such trials with varying designs have been performed to date. In one trial of combination therapy Clyde, et al.[146] compared levothyroxine alone for treatment of primary hypothyroidism with combination therapy using levothyroxine plus liothyronine. These investigators demonstrated no beneficial changes in body weight, serum lipid levels, hypothyroid symptoms as measured by a health-related quality-of-life questionnaire, and standard measures of cognitive performance.[146] Two metaanalyses have also suggested no benefits.[147,148] However, a recent study, suggested that individuals harboring a specific deiodinase polymorphism may have a poorer psychological response to levothyroxine therapy and a better response to combination therapy with both T_4 and T_3

Natural Thyroid Hormones

Desiccated thyroid is derived from hog, beef, or sheep thyroid gland. The United States Pharmacopeia, 23th ed., requires Thyroid USP to contain 38 mcg (±15%) of levothyroxine and 9 mcg (±10%) of liothyronine for each 65 mg (1 grain) of the labeled content of TG. Thyroglobulin USP should contain 36 mcg (±15%) of levothyroxine and 12 mcg (±10%) of liothyronine for each 65 mg (1 grain) of the labeled content of TG. Not all generic brands may be bioequivalent, and switching among brands for patients stabilized on one product should be discouraged. Thyroid USP, as an animal protein–derived product, may be antigenic in allergic or sensitive patients. Even though desiccated thyroid is inexpensive, its limitations preclude it from being considered as a drug of choice for hypothyroid patients. TG is a purified hog-gland extract, but it has no clinical advantages and is not widely used.

Dosing and Monitoring Recent studies suggest that the average maintenance dose of levothyroxine for most adults is about 125 mcg/day.[117] The replacement dose of levothyroxine is affected by body weight. Estimates of weight-based doses for replacement in hypothyroid patients include 1.6 mcg/kg/day and 1.7 mcg/kg/day.[149,150] There is, however, a wide range of replacement doses, necessitating individualized therapy and appropriate TSH monitoring to determine an adequate but not excessive dose.

In addition to alleviation of symptoms, the goal of treatment for patients with hypothyroidism is to maintain the patient's TSH within the normal range. Some clinicians are of the opinion that the traditional reference range of approximately 0.5 to 4.5 milli-international units/L includes at its upper end some individuals who have unrecognized thyroid disease.[151] Thus, some believe that the reference range should be modified downwards to 0.5 to 3.5 milli-international units/L or even 0.5 to 2.5 milli-international units/L.[152] If this premise is accepted, both the TSH values that trigger levothyroxine treatment and the TSH treatment goal could potentially be altered. There are cogent arguments on both sides of the issue. Those who would suggest maintaining current reference ranges believe that changes would result in the treatment with thyroid hormone of many individuals who would not necessarily benefit from treatment.[153] Those who favor narrowing the range suggest that additional patients would derive benefit from thyroid hormone treatment.[152] TSH reference ranges also differ for different populations, such as those who are pregnant, specific ethnic groups, and older individuals.

The required dose of levothyroxine is dependent on the patient's age[154] and the presence of associated disorders, as well as the severity and duration of hypothyroidism.[155] Most patients will require approximately 1.7 mcg/kg/day once they reach steady state for full replacement. Dose requirement may be better estimated based on ideal body weight, rather than actual body weight.[156] In young patients with long-standing disease and patients over age 45 without known cardiac disease, therapy should be initiated with 50 mcg daily of levothyroxine and increased to 100 mcg daily after 1 month. The recommended initial daily dose for older patients or those with known cardiac disease is 25 mcg per day titrated upward in increments of 25 mcg at monthly intervals to prevent stress on the cardiovascular system. Some patients may experience an exacerbation of angina with higher doses of thyroid hormone. Although the TSH is an indicator of under- or overreplacement, clinicians often fail to alter the dose of T_4 based on TSH clearly outside of the normal range.[157,158]

Patients with subclinical or mild hypothyroidism (seen more commonly for the elderly and women) have no or few signs

or symptoms, normal serum T_3 and T_4 concentrations, and an elevated basal TSH concentration.[159,160] The prevalence of this disorder in the Third National Health and Nutrition Examination Survey (NHANES III) study was found to be 4.3%.[21] Although the treatment of subclinical hypothyroidism is controversial, patients presenting with marked elevations in TSH (>10 milli-international units/L) and high titers of thyroid peroxidase antibody (TPOAb) or prior treatment with ^{131}I may be most likely to benefit from treatment. Other patients who may improve with replacement include those with mild symptoms of hypothyroidism and depression. It should be noted that some studies find that only 1 of 4 treated patients experienced improvement.[161] Conservative treatment goals in this situation would be to maintain serum T_4 and T_3 levels in the normal range and reduce TSH to a value of 1 milli-international unit/L.

Once euthyroidism is attained, the daily maintenance dose of levothyroxine does not fluctuate greatly. As patients age, the dosing requirement may be reduced.[129] Third generation TSH assays improved the accuracy with which thyroid hormone replacement can be monitored. The TSH concentration is the most sensitive and specific monitoring parameter for adjustment of levothyroxine dose. Plasma TSH concentrations begin to fall within hours and are usually normalized within 2 weeks, but they may take up to 6 weeks for some patients, depending on the baseline value. TSH and T_4 concentrations are both used to monitor therapy, and they should be checked every 6 weeks until a euthyroid state is achieved. Laboratory assessment of thyroid function should be performed approximately 6 weeks after levothyroxine dose initiation or change. This time frame allows achievement of steady state, as the half-life of levothyroxine is approximately 1 week. Serum T_4 concentrations can be useful in detecting noncompliance, malabsorption, or changes in levothyroxine product bioequivalence. An elevated TSH concentration indicates insufficient replacement. The appropriate dose maintains the TSH concentration in the normal range. Thyroxine disposal is accelerated by nephritic syndrome, other severe systemic illnesses, and several antiseizure medications (phenobarbital, phenytoin, and carbamazepine) and rifampin. Pregnancy increases the thyroxine dose requirement for 75% of women, probably because of factors such as increased degradation by the placental deiodinase, increased T_4 pool size, and transfer of T_4 to the fetus. The etiology of hypothyroidism also affects the magnitude of the dosage increase.[162] Initiating postmenopausal hormone replacement therapy increases the dose needed in 35% of women, perhaps due to an increased circulating TBG level. Patient noncompliance with prescribed thyroxine, the most common cause of inadequate treatment, might be suspected for patients with a dose that is higher than expected, variable thyroid function test results that do not correlate well with prescribed doses, and an elevated serum thyrotropin concentration with serum free thyroxine at the upper end of the normal range, which can suggest improved compliance immediately before testing due to a lag in the thyrotropin response. The metabolism of other pharmacologic agents can be altered for patients with hypothyroidism. The mechanism might be decreased expression of hepatic enzymes involved in drug metabolism, as seen in hypothyroid rats. As a result, increased sensitivity to anesthetic and sedative agents, and higher serum levels of phenytoin have been reported. Hypothyroidism can also cause higher serum digoxin values, an effect attributed to a decreased volume of drug distribution. Conversely, hypothyroidism might decrease sensitivity to warfarin due to slowed metabolism of the vitamin K–dependent clotting factors, and restoration of euthyroidism can then increase the warfarin dose requirement.

For patients with central hypothyroidism caused by hypothalamic or pituitary failure, the serum TSH cannot be used to assess adequacy of replacement. Alleviation of the clinical syndrome and restoration of serum T_4 to the normal range are the only criteria available for estimating the appropriate replacement dose of levothyroxine. Concurrent use of dopamine, dopaminergic agents (bromocriptine), somatostatin or somatostatin analogs (octreotide), and corticosteroids suppresses TSH concentrations in individuals with primary hypothyroidism and may confound the interpretation of this monitoring parameter.[129]

TSH-suppressive levothyroxine therapy can be given to patients with nodular thyroid disease and diffuse goiter, to patients with a history of thyroid irradiation, and to patients with thyroid cancer. The rationale for suppression therapy is to reduce TSH secretion, which promotes growth and function in abnormal thyroid tissue. However, such management, other than for patients with thyroid cancer or with elevated TSH levels, is quite controversial. Some clinicians rarely recommend or use such therapy; others will recommend a trial of levothyroxine as suppressive therapy in some patients. The conclusions of three metaanalyses were that suppressive therapy for nodules was associated with a small decrease in nodule growth,[163] a statistically nonsignificant reduction in nodule growth,[164] and a significant reduction in nodule growth that was reduced with longer term treatment.[165] If suppressive therapy with levothyroxine is pursued, the age, gender, and menopausal status of the patient need to be considered, along with the risk of cardiac arrhythmias and reduced bone mineral density. Levothyroxine may be given in nontoxic MNG to suppress the TSH to low-normal levels of 0.5 to 1 milli-international unit/L if the baseline TSH is >1 milli-international unit/L. Goiter size and thyroid volume may be reduced with suppression therapy. Diffuse goiter associated with autoimmune thyroiditis may also be treated with levothyroxine to reduce goiter size and thyroid volume. Levothyroxine suppression therapy is of benefit to all but the lowest risk thyroid cancer patients and is generally used in the management of patients with differentiated thyroid cancer, with the TSH goal being influenced by the patient's thyroid cancer stage and other risk factors.[166] Current guidelines from the American Thyroid Association suggest suppressing the TSH to below 0.1 milli-international unit /L in higher risk patients, keeping TSH around the lower limit of normal (0.1 to 0.5 milli-international units/L) in low-risk patients.[167]

Adverse Effects Serious untoward effects are unusual if dosing is appropriate and the patient is carefully monitored during initial treatment. A cross-sectional study showed that of a population of 1,525 individuals taking levothyroxine, 40% actually had abnormal TSH values.[168] A recent study showed that 57% of individuals 65 years or older receiving thyroid hormone treatment had abnormal TSH values.[169] Both of these studies suggest failure to keep a patient's TSH at goal is common. Levothyroxine replacement in athyreotic hypothyroid patients restores systolic and diastolic left ventricular performance within 2 weeks, and the use of levothyroxine may increase the frequency of atrial premature beats but not necessarily ventricular premature beats. Excessive doses of thyroid hormone may lead to heart failure, angina pectoris, and myocardial infarction; rarely, the latter may be caused by coronary artery spasm. Allergic or idiosyncratic reactions can occur with the natural animal-derived products such as desiccated thyroid and TG, but these are extremely rare with the synthetic products used today. The 0.05 mg (50 mcg) Synthroid tablet is the least allergenic (due to a lack of dye and few excipients) and should be tried for the patient suspected to be allergic to thyroid hormone.

Hyperremodeling of cortical and trabecular bone due to hyperthyroidism leads to reduced bone density and may increase the risk of fracture. Compared with normal controls, excess exogenous thyroid hormone results in histomorphometric and biochemical changes similar to those observed in osteoporosis and untreated hyperthyroidism; however, at routinely used replacement doses,

bone mineral density loss is less than that seen with untreated hyperthyroidism and only slightly greater than in controls.[170,171] The risk for this complication of therapy seems to be related to the dose of levothyroxine, patient age, and gender. Markers for bone turnover include urinary cross-linked *N*-telopeptides, pyridinoline of type I collagen, osteocalcin, and bone-specific alkaline phosphatase. When doses of levothyroxine are used to suppress TSH concentrations to below-normal values (less than 0.3 milli-international unit/L) in postmenopausal women, this adverse effect is more likely to be seen. Cortical bone is affected to a greater degree than trabecular bone at suppressive doses of levothyroxine. In contrast, it appears to be much less likely in men and in premenopausal women. Maintaining the TSH between 0.7 and 1.5 milli-international units/L does not alter bone mineral density in premenopausal women.

EVALUATION OF THERAPEUTIC OUTCOMES

HYPOTHYRODISM

Patients on optimal thyroid hormone replacement therapy should have TSH and free T_4 serum concentrations in the normal range. Those who are being treated for thyroid cancer should have TSH suppressed to low levels based on their risk stratification[167] and their TG should be undetectable. Given the half-life of 7 days of T_4, the appropriate monitoring interval is no more often than 4 weeks. The signs and symptoms of hypothyroidism should be improved or absent (see Clinical Presentation of Hypothyroidism above), although this may take several months for most to improve.

SPECIAL CONDITIONS

Myxedema Coma

Myxedema coma is a rare consequence of decompensated hypothyroidism.[172,173] Clinical features include hypothermia, advanced stages of hypothyroid symptoms, and altered sensorium ranging from delirium to coma. Mortality rates of 60% to 70% necessitate immediate and aggressive therapy. Traditionally, the initial treatment has been intravenous bolus levothyroxine 300 to 500 mcg. However, as deiodinase activity is markedly reduced, impairing T_4 to T_3 conversion, initial treatment with intravenous triiodothyronine or a combination of both hormones has also been advocated.[173] Glucocorticoid therapy with intravenous hydrocortisone 100 mg every 8 hours should be given until coexisting adrenal suppression is ruled out. Consciousness, lowered TSH concentrations, and normal vital signs are expected within 24 hours. Maintenance doses of levothyroxine are typically 75 to 100 mcg given intravenously until the patient stabilizes and oral therapy is begun. Supportive therapy must be instituted to maintain adequate ventilation, euglycemia, blood pressure, and body temperature. Any underlying disorder, such as sepsis or myocardial infarction, obviously must be diagnosed and treated.

Congenital Hypothyroidism[174]

In congenital hypothyroidism, full maintenance therapy should be instituted early to improve the prognosis for mental and physical development.[175] The average maintenance dose in infants and children depends on the age and weight of the child. Several studies demonstrate that aggressive therapy with levothyroxine is important for normal development, and current recommendations are for initiation of therapy within 45 days of birth at a dose of 10 to 15 mcg/kg/day.[124] This dose is used to keep T_4 concentrations at about 10 mcg/dL within 30 days of starting therapy and is associated with improved IQs in treated infants. The dose is progressively decreased to a typical adult dose as the child ages, the adult dose being given in the age range of 11 to 20 years.

Hypothyroidism in Pregnancy[99]

Hypothyroidism during pregnancy leads to an increased rate of stillbirths and possibly lower psychological scores in infants born of women who received inadequate replacement during pregnancy.[176] Thyroid hormone is necessary for fetal growth and must come from the maternal side during the first 2 months of gestation. Although liothyronine may cross the placental membrane slightly better than levothyroxine, the latter is considered the drug of choice. The objective of treatment is to decrease TSH to 1 unit/mL and maintain free T_4 concentrations in the normal range. Based on elevated TSH levels during pregnancy, it was found that the mean dose of levothyroxine had to be increased by 36 mcg/day to suppress TSH into the normal range. Increased production of binding proteins, a marginal decrease in free hormone concentration, modification of peripheral thyroid hormone metabolism, and increased thyroxine metabolism by the fetal–placental unit also contributes to increased thyroid hormone demand and the need for increased doses decreases after delivery.[100] Up to 60% of women need to have levothyroxine dose adjustment during pregnancy. Upward adjustment will be needed by the 8th week of pregnancy. The etiology of the hypothyroidism affects the magnitude of the required increase in levothyroxine dose.[162] After delivery the levothyroxine dose can be reduced based on T_4 concentrations and measurement of TSH, typically about 6 to 8 weeks after delivery.[99] Many patients can return to their prepregnancy dose requirement.

Effects of Hypothyroidism on Selected Medications

Hypothyroidism may affect the metabolism and clinical efficacy of several medications. Digitalis preparations have a decreased volume of distribution in the hypothyroid state, resulting in increased sensitivity to the digitalis effect. Therefore, many hypothyroid patients achieve a therapeutic effect at lower digitalis doses. Insulin degradation may be delayed in hypothyroidism, thereby requiring a lower insulin dose. Hypothyroidism delays the catabolism of clotting factors, and if a patient stabilized on warfarin is made euthyroid with levothyroxine, the patient may become excessively anticoagulated. Respiratory depressants such as barbiturates, phenothiazines, and opioid analgesics should be avoided, because increased sensitivity may increase carbon dioxide retention and precipitate myxedema coma.

RECOMBINANT TSH IN THYROID CANCER

Patients with previously treated differentiated (papillary, follicular, or their respective variants) thyroid carcinoma require lifelong monitoring for recurrent disease.[177,178] Two diagnostic tests that play a central role in the follow-up of these patients—serum TG measurement and radioiodine whole body scanning—are most accurate during TSH stimulation. Temporary discontinuation of thyroid hormone therapy was previously the sole effective approach for TSH-stimulated testing. However, hormone withdrawal is associated with the morbidity of hypothyroidism and occasional tumor progression. The introduction of recombinant TSH (rTSH)-stimulated testing offers an alternative therapy. Recent clinical trials have shown that the sensitivity of combined rTSH-stimulated radioiodine scanning and serum TG measurement has nearly equivalent sensitivity to testing after thyroid hormone withdrawal.[127,179] Furthermore, measurement of the rTSH-stimulated TG concentration is a more sensitive way to detect residual thyroid cancer or normal tissue than TG measurement on thyroid hormone

therapy. Postthyroidectomy adjuvant radioiodine therapy can also be administered following rTSH, instead of thyroid hormone withdrawal, with equivalent rates of remnant ablation.[180] Patients for whom thyroid hormone withdrawal would be contraindicated may also be successfully treated with radioiodine following rTSH.[181] A recent study reporting short-term follow-up of 3.7 years on patients receiving their remnant ablation with rTSH showed that rates of residual and recurrent thyroid cancer did not differ between patients prepared for receiving radioiodine using rTSH versus withdrawal from levothyroxine.[182] Recently rTSH has also been used successfully to aid in the treatment of large, compressive goiters in individuals who are not surgical candidates. Radioiodine treatment, delivered following small doses of rTSH, can lead to improved radioiodine uptake and reduced goiter volume,[183] although this is not yet an approved use of rTSH.

NONTHYROIDAL ILLNESS

A wide variety of abnormalities of hypothalamic–pituitary–thyroid function, serum thyroid hormone binding, and extrathyroidal thyroid hormone metabolism occurs in patients with nonthyroidal illness.[13,14] These abnormalities frequently result in decreased serum T_3 concentrations and, with more severe nonthyroidal disease, lead to a decreased serum free T_4 concentration as well. Serum TSH concentrations are initially within the normal range but then tend to decrease with increasing severity of illness. The presence of coexisting primary hypothyroidism can be recognized for patients who have other illnesses by an elevation in the TSH concentration.

The degree and extent of the abnormality in thyroid function generally correlates with the severity of the nonthyroidal illness. These conditions are frequently referred to as the *euthyroid sick syndrome*. However, it is likely that these changes represent adaptive forms of hypothyroidism that serve to reduce the availability of thyroid hormones to lessen the catabolic impact of the nonthyroidal illness.

Decreased serum T_3 concentrations occur in patients with both acute and chronic illnesses. The fundamental cause of decreased serum T_3 concentrations in these situations is decreased extrathyroidal conversion of T_4 to T_3, normally mediated by T_4-5′-deiodinase. A circulating inhibitor of this enzyme, perhaps interleukin-6, is present in patients with nonthyroidal illness.[184] Serum total and free T_4 concentrations are usually normal in mild illness. The serum reverse T_3 concentration is characteristically high because the same enzyme, 5′-deiodinase, that is necessary to convert T_4 to T_3 is necessary to convert reverse T_3 to its breakdown products.

Low serum T_4 is seen in most critically ill patients.[185–187] This change is caused by diminished serum T_4 synthesis as well as impaired binding to serum transport proteins, resulting either from decreased serum concentrations of thyroid-binding globulin, thyroid-binding prealbumin, or albumin, or from inhibitors of T_4 binding. The free T_4 concentration is generally normal early in critical illness but also declines with more severe disease. This more severe degree of hypothyroidism, which occurs in severely ill patients, produces a greater reduction in thyroid hormone availability. The low serum T_4 concentrations for patients with nonthyroidal illness indicate a grave prognosis. In two studies, more than 60% of hospitalized patients with a low serum free T_4 index died. Although controversial, T_4 or T_3 supplementation has been of no benefit in this situation.[188]

To confuse matters, some patients with nonthyroidal illness have elevation of their serum T_4 concentration. Most commonly, this is seen in patients with psychiatric disorders during acute psychotic breaks. Thyroid hormone levels return to normal within 2 weeks after successful treatment of the underlying psychiatric disease. The occurrence of these abnormalities requires that care be taken in diagnosing hypothyroidism or hyperthyroidism for patients who have nonthyroidal illnesses.

GOITROUS THYROID DISEASE

Endemic goiter is the major thyroid disease throughout the world, affecting more than 200 million people. Many goitrous glands contain one or more nodules. The introduction of iodide supplementation has eliminated goiter as a major medical problem in developed countries, though it continues to be a problem in developing countries whose geographic position makes them more susceptible to iodide deficiency. In 1924, Marine postulated that periods of iodide deficiency resulted in cyclic hyperplasia and involution of thyroid follicular cells with eventual development of nodular hyperplasia.[47,189] This hypothesis is still used to explain goiter formation today. Whatever the specific cause, the final common pathway appears to result from an inadequate thyroid hormone secretion with compensatory TSH secretion and eventual thyroid gland enlargement. The essential factor for the conversion of a hyperplastic iodine-deficiency goiter into a colloid goiter appears to be an acute reduction of TSH stimulation; therefore, any situation that would result in a cyclical increase and decrease in TSH secretion might eventually result in the production of a nodular goiter.

There has been an interest in the possibility that growth factors other than TSH play a role in the development of a goiter. Immunoglobulin fractions capable of stimulating thyroid growth have been found in patients with nontoxic goiter and Graves's disease. In these patients, thyroid growth–promoting immunoglobulin titers correlate with goiter size rather than with the thyroid hormone concentration.

Sporadic goiter is defined as a goiter occurring in a nonendemic goiter region. Although a number of known goitrogens and errors in thyroid hormone biosynthesis may cause goiter, the majority of cases of sporadic goiter have no known etiology.

Treatment of goiters can include a trial of thyroid hormone suppression in an effort to eliminate TSH as a possible stimulus for continued thyroid growth. Large, long-standing goiters seldom undergo significant reduction in size. If the patient is symptomatic (with dysphagia or dyspnea) or there is a question of malignant thyroid involvement, surgery is recommended.

PHARMACOECONOMIC CONSIDERATIONS

Although the initial expense of surgery would seem to make it the most expensive treatment option for hyperthyroidism, the relapse rates for thionamides and RAI are higher, and in longer-term follow-up there is not much difference between treatment options nor patients' opinions concerning treatment preferences as suggested by a 1998 study.[190] The cost proportion between the medical and surgical treatment in younger patients is 1:2.5 (1 = U.S.$1,126) before and 1:1.3 (1 = U.S. $2,284) after inclusion of the relapse costs. The proportion between the medical, surgical, and ^{131}I treatment in older patients is 1:2.5:1.6 (1 = U.S. $1,164) before and 1:1.6:1.4 (1 = U.S. $1,972) after inclusion of the relapse costs.

Multiple studies have addressed the role of thyroid supplementation in critically ill patients with cardiac disease, sepsis, pulmonary disease (e.g., acute respiratory distress syndrome), or severe infection, or with burn and trauma patients. In spite of a very large number of published studies, it is very difficult to form clear recommendations for treatment with thyroid hormone in the intensive care unit.[188]

CLINICAL CONTROVERSIES

Although the current FDA standards of bioavailability for thyroxine products suggest that several products are bioequivalent, the relationship between T_4 serum concentration and TSH response suggests that the products are not truly bioequivalent. New standards of bioequivalency may need to be developed for drug products like thyroxine.

Combination therapy of $T_4 + T_3$ for hypothyroidism generally offers no objective advantage over monotherapy, although subjective patient improvement or patient preference for combination therapy has been reported in a minority of studies. However, recent data suggest that patients with certain deiodinase polymorphisms may, in fact, derive a psychological benefit from combination therapy.

Multiple studies have addressed the role of thyroid supplementation for critically ill patients with cardiac disease, sepsis, pulmonary disease (e.g., acute respiratory distress syndrome), or severe infection or for patients with burn and trauma. In spite of a very large number of published studies, it is very difficult to form clear recommendations for treatment with thyroid hormone in the intensive care unit.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients with idiopathic hypothyroidism and Hashimoto's thyroiditis on optimal thyroid hormone replacement therapy should have TSH and free T_4 serum concentrations in the normal range. Those who are being treated for thyroid cancer should have TSH suppressed to low levels, with the appropriate TSH concentration being determined based on the patient's risk of recurrence or progression, and TG should be undetectable. Given the half-life of T_4 of 7 days, the appropriate monitoring interval is no more often than 4 weeks. The signs and symptoms of hypothyroidism should be improved or absent (see Clinical Presentation of Hypothyroidism above), although this may take several months for most to improve.

ABBREVIATIONS

ClO_4^-: perchlorate

DIT: diiodotyrosine

FSH: follicle-stimulating hormone

$G_s\alpha$: the α subunit of the stimulatory guanine-nucleotide–binding protein

hCG: human chorionic gonadotropin

HLA: human leukocyte antigen

^{131}I: sodium iodide 131

l-thyroxine: levothyroxine

LH: luteinizing hormone

MIT: monoiodotyrosine

MMI: methimazole

MNG: multinodular goiter

PRTH: pituitary resistance to thyroid hormone

PTU: propylthiouracil

RAI: radioactive iodine

RAIU: radioactive iodine uptake

rTSH: recombinant thyroid-stimulating hormone

SCN^-: thiocyanate

SSKI: saturated solution of potassium iodide

T_3: triiodothyronine

T_4: thyroxine

TBG: thyroid-binding globulin

TBPA: thyroid-binding prealbumin

TcO_4^-: pertechnetate

TG: thyroglobulin

TPOAb: thyroperoxidase antibodies

TRβ2, TRβ1, TRα1: thyroid hormone receptors

TRH: thyrotropin-releasing hormone

TSAb: thyroid-stimulating antibody

TSH: thyroid-stimulating hormone

CHAPTER 85

Adrenal Gland Disorders

STEVEN M. SMITH AND JOHN G. GUMS

KEY CONCEPTS

1. Glucocorticoid secretion from the adrenal cortex is stimulated by adrenocorticotropic hormone (ACTH) or corticotropin that is released from the anterior pituitary in response to the hypothalamic-mediated release of corticotropin-releasing hormone (CRH).
2. To ensure the proper treatment of Cushing's syndrome, diagnostic procedures should (1) establish the presence of hypercortisolism and (2) discover the underlying etiology of the disease.
3. The rationale for treating Cushing's syndrome is to reduce the morbidity and mortality resulting from disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities.
4. The treatment of choice for both ACTH-dependent and ACTH-independent Cushing's syndrome is surgery, whereas pharmacologic agents are reserved for adjunctive therapy, refractory cases, or inoperable disease.
5. Pharmacologic agents that may be used to manage the patient with Cushing's syndrome include steroidogenesis inhibitors, adrenolytic agents, neuromodulators of ACTH release, and glucocorticoid-receptor blocking agents.
6. Spironolactone, a competitive aldosterone receptor antagonist, is the drug of choice in bilateral adrenal hyperplasia (BAH)-dependent hyperaldosteronism.
7. Addison's disease (primary adrenal insufficiency) is a deficiency in cortisol, aldosterone, and various androgens resulting from the loss of function of all regions of the adrenal cortex.
8. Secondary adrenal insufficiency usually results from exogenous steroid use, leading to hypothalamic-pituitary-adrenal (HPA)-axis suppression followed by a decrease in ACTH release, and low levels of androgens and cortisol.
9. Virilism results from the excessive secretion of androgens from the adrenal gland and often manifests as hirsutism in females.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The adrenal glands were first characterized by Eustachius in 1563. After Addison identified a case of adrenal insufficiency in humans, adrenal anatomy and physiology flourished. Most of the work done in the early and mid-1900s centered on the glucocorticoid cortisol. With the discovery of aldosterone by Simpson and Tait in 1952, adrenal pharmacology turned toward the mineralocorticoid. Conn[1] followed with his classical description of primary aldosteronism in 1955, and numerous clinicians and investigators have continued to explore the variety of disease processes promoted through the adrenal gland.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY

The adrenal glands are located extraperitoneally to the upper poles of each kidney (Fig. 85–1). On average, each adrenal gland weighs 4 g and is 2 to 3 cm in width and 4 to 6 cm in length. The gland is fed by small arteries from the abdominal aorta and renal and phrenic arteries. Drainage of the adrenal gland occurs via the renal vein on the left and the inferior vena cava on the right.

The adrenal medulla occupies 10% of the total gland and is responsible for the secretion of catecholamines. The adrenal cortex accounts for the remaining 90% and is responsible for the secretion of three types of hormones (Fig. 85–2) from three separate zones.

The zona glomerulosa accounts for 15% of the total adrenal cortex and is responsible for mineralocorticoid production, of which aldosterone is the principal end product. Aldosterone maintains electrolyte and volume homeostasis by altering potassium and magnesium secretion and renal tubular sodium reabsorption. The zona fasciculata, the middle zone, makes up 60% of the cortex,

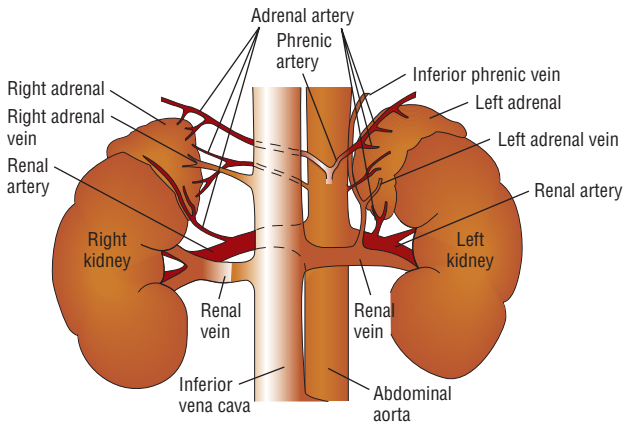

FIGURE 85-1. Anatomy of the adrenal gland.

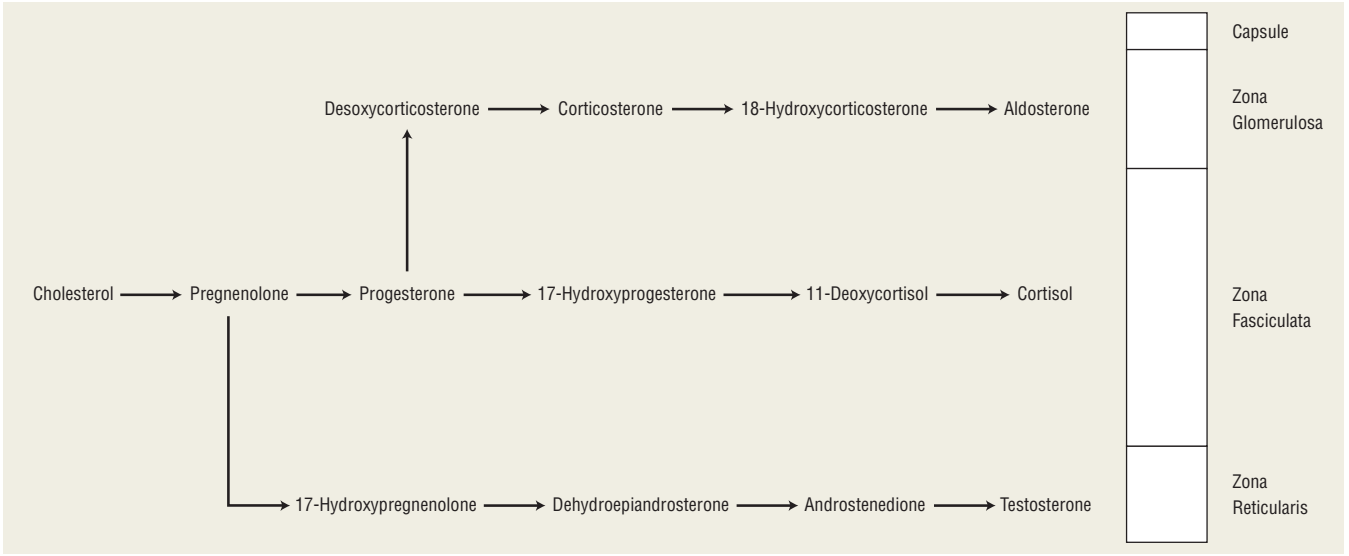

FIGURE 85-2. Hormone synthetic pathways in relation to the zones of the adrenal cortex.

is high in cholesterol, and is responsible for basal and stimulated glucocorticoid production. Glucocorticoids, mainly cortisol, are responsible for the regulation of fat, carbohydrate, and protein metabolism. The zona reticularis occupies 25% of the adrenal cortex, and is responsible for adrenal androgen production. The androgens, testosterone and estradiol, are the major end products and influence the reproductive system in addition to modulating primary and secondary sex characteristics.

HORMONE PRODUCTION AND METABOLISM

Adrenal steroid hormone synthesis begins with the conversion of cholesterol to pregnenolone by cytochrome P450 (CYP) enzymatic side-chain cleavage. Following this rate-limiting step, pregnenolone is converted to various 19- and 21-carbon steroids, depending on the enzymatic capabilities within each zone of the cortex. Androgenic properties predominate in the 19-carbon steroids, whereas mineralocorticoid and glucocorticoid properties manifest in the 21-carbon steroids.

Aldosterone production is initiated by the 21-hydroxylation of progesterone to form deoxycorticosterone. Subsequently, aldosterone synthase converts deoxycorticosterone to aldosterone through the intermediary, corticosterone. The zona glomerulosa preferentially produces aldosterone for three main reasons. First, the zona glomerulosa lacks 17α-hydroxylase activity and therefore can only convert pregnenolone to progesterone. Secondly, in contrast to the other zones, cells in the zona glomerulosa possess aldosterone synthase activity, which catalyzes the terminal steps in aldosterone synthesis. Lastly, cells of the zona glomerulosa display a greater number of angiotensin II receptors than cells of the other zones. Binding of angiotensin II to these receptors provides the stimulus for initiating the aldosterone biosynthesis cascade. Thus, aldosterone synthesis is a unique feature of the zona glomerulosa, explaining why aldosterone is not affected during disease processes limited to the fasciculata and/or reticularis.

Cortisol is produced from pregnenolone via four successive hydroxylations. These hydroxylations occur primarily in the zona fasiculata although the zona reticularis is also capable of producing glucocorticoids.

Androgens, produced primarily in the zona reticularis and less commonly in the zona fasiculata, have a 19-carbon structure and serve as precursors to more potent analogs produced in the periphery. The adrenal gland can synthesize estradiol and estrone from testosterone and androstenedione, respectively; however, these synthesized quantities are extremely small. The rates of production for the various steroids produced by the adrenal gland are listed in Table 85–1.

Glucocorticoid metabolism occurs in the liver and is responsible for converting inactive steroids to active metabolites, as well as modifying active steroids to less active or inactive metabolites. Most pharmaceutical steroid products are active; however, in the case of prednisone and cortisone, metabolism is necessary for conversion to the active prednisolone and cortisol, respectively.

Following metabolic conversion, glomerular filtration is primarily responsible for eliminating endogenously produced glucocorticoids. The half-life of cortisol is 70 to 120 minutes, whereas aldosterone exhibits extremely high intrinsic clearance and a corresponding half-life of only 15 minutes.

Metabolism and conversion of the various steroids can be altered by a variety of disease states and medicinal compounds. Drugs known to enhance steroid clearance include phenytoin, phenobarbital, rifampin, mitotane, and aminoglutethimide. Likewise, diseases

TABLE 85-1 Rates of Adrenal Production and Plasma Concentrations of Various Steroids

Steroid	24-Hour Secretion (mg)	Plasma Concentration (ng/dL)
Aldosterone	0.15	2–9 (supine, normal-sodium diet)
Androstenedione	2.2–2.5	50–250
Corticosterone	1–4	2.4 ± 1.5 (female) 4.2 ± 2.2 (male)
Cortisol	8–25	0–25 mcg/DL
11-Deoxycorticosterone	0.60	2–19
11-Deoxycortisol	0.40	12–158
Progesterone	0.0	<20 (female)[a] 300–2,000 (female)[b] <20–140 (male)
Testosterone (total)	0.23 (female)	6–86 (female) 270–1070 (male)

[a]Follicular phase of menstrual cycle.
[b]Luteal phase of menstrual cycle.

such as hyperthyroidism and renal disease (dexamethasone only) can enhance steroid clearance. In contrast, drugs such as estrogens and estrogen-containing oral contraceptives reduce steroid clearance. Similarly, liver disease, age, pregnancy, hypothyroidism, anorexia nervosa, protein-calorie malnutrition, and renal disease (prednisolone only) are associated with reduced steroid clearance.

Plasma glucocorticoids are bound to one of three plasma proteins in varying degrees. Corticosteroid-binding globulin (CBG), albumin, and α_1-glycoprotein are capable of binding glucocorticoids, with CBG being the principal binding protein. Steroid binding serves as a reservoir for steroids in their inactive state and ≥95% of cortisol is normally bound in this fashion. This binding prevents glucocorticoid activity at receptor-activating sites. Therefore, a final but important variable in altered plasma concentration of free (active) steroids is concentration of plasma proteins.

REGULATION OF HORMONE SECRETION

1 Glucocorticoid secretion is regulated by the pituitary hormone, ACTH (also known as corticotropin). Under normal conditions, ACTH is released from the anterior pituitary in response to CRH, which is secreted by the median eminence of the hypothalamus (Fig. 85–3). Vasopressin and oxytocin have weak ACTH-releasing activity through binding to the inferior V_3 receptor. CRH, in combination with vasopressin and oxytocin, stimulates greater ACTH secretion than each hormone individually.

Additionally, histochemical studies have demonstrated that certain neurotransmitters have the unique ability to stimulate production of CRH or ACTH directly. Specifically, 5-hydroxytryptamine and norepinephrine have both been shown to increase levels of ACTH. After release, ACTH stimulates the adrenal gland to release cortisol and, to a lesser extent, aldosterone and androgens. The rising cortisol concentration inhibits the secretion of CRH and ACTH through a negative-feedback mechanism. In addition, leptin, an adipocyte hormone, can have an inhibitory effect on HPA activity.

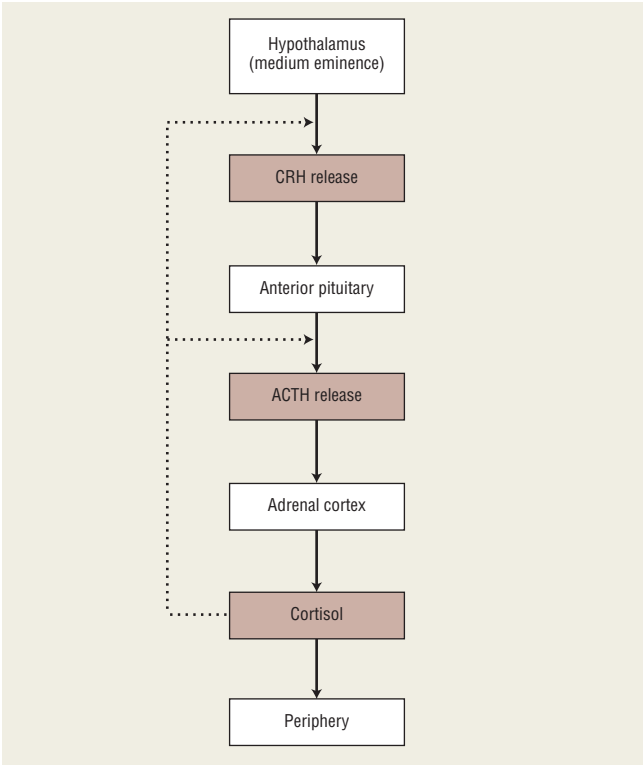

FIGURE 85-3. Negative feedback system involved in the regulation of cortisol secretion under normal conditions. (ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.)

Adrenal androgens are regulated in a similar fashion to cortisol. When plasma androgen reaches sufficient concentrations, production is terminated via a negative feedback loop. Androgen release is increased during puberty and in women with hirsutism. Adrenal androgen release decreases with age and in fasting states, including anorexia nervosa.

In contrast to cortisol and adrenal androgens, regulation of aldosterone secretion is considerably more complex. The renin-angiotensin system regulates aldosterone secretion through both intrarenal and extrarenal mechanisms. Renin production and subsequent aldosterone secretion is stimulated by blood pressure lowering (due to volume depletion), erect posture, salt depletion, β-adrenergic stimulation, and central nervous system excitation (see Chap. 15). Renin production is inhibited by salt loading, angiotensin II, vasopressin, potassium, calcium, blood pressure increases, and a variety of drugs. The renin-mediated production of angiotensin II is the initial stimulus for aldosterone synthesis. Additionally, angiotensin II can be acted on by aminopeptidase and converted to angiotensin III. Angiotensin II and III are both capable of stimulating the zona glomerulosa to secrete aldosterone. Following aldosterone secretion, increases in renal sodium and water retention as well as blood pressure occur, thereby turning off the stimulus for renin release.

HYPERFUNCTION OF THE ADRENAL GLAND

CUSHING'S SYNDROME

In 1932, Cushing first described a syndrome of pituitary basophilism that attracted national attention. Until this time, no definitive diagnosis existed for patients with unexplained central obesity, cutaneous striae, osteoporosis, weakness, hypertension, diabetes mellitus, and congestion. Cushing emphasized that the disease was of a pituitary origin. Ten years later, Albright focused his attention on the sugar hormone, which he believed originated from the adrenal cortex.[2]

After the development of a method for measuring urinary steroids, Daughaday discovered elevated steroids in the urine of patients with Cushing's syndrome. Finally, the end product was identified, and Cushing's syndrome was correctly explained as an excess of cortisol in the plasma (hypercortisolism).

Etiology

Cushing's syndrome results from the effects of supraphysiologic levels of glucocorticoids originating either from exogenous administration or less commonly, from endogenous overproduction by the adrenal glands. Excess glucocorticoids are produced in response to overproduction of ACTH (ACTH-dependent) or by abnormal adrenocortical tissues regardless of ACTH stimulation (ACTH-independent). ACTH-dependent Cushing's syndrome (≈80% of all Cushing's cases) usually originates from overproduction of ACTH by the pituitary gland, which chronically stimulates the adrenal glands causing bilateral adrenal hyperplasia. Approximately 85% of these cases are caused by pituitary adenomas (Cushing's disease). Ectopic ACTH-secreting tumors and non-neoplastic corticotropin hypersecretion, possibly secondary to excess CRH production, account for the remainder of ACTH-dependent causes.[3] Ectopic ACTH syndrome refers to excessive ACTH production resulting from an endocrine or nonendocrine tumor, usually of the pancreas, thyroid, or lung. Small-cell carcinoma of the lung will lead to ectopic ACTH secretion in 0.5% to 2% of cases, whereas bronchial carcinoid tumors are usually the most common.[4] Distinguishing

TABLE 85-2 Various Etiologies of Cushing's Syndrome and Their Respective Differences

	Pituitary-Dependent	Ectopic ACTH Syndrome	Adrenal Adenoma	Adrenal Carcinoma
Course	Slow	Rapid	Slow	Rapid
Symptoms	Mild to moderate	Atypical	Mild to moderate	Severe
Dominant sex/age	Female/male	Male	None noted	Children
Virilization	+	+	+	+++
Abdominal mass	0	0	0	++
Plasma ACTH concentration	Slightly elevated	High	0	0
Dexamethasone suppression test	≥50% Suppression	No suppression	No suppression	No suppression
Iodocholesterol scan	Bilateral uptake	Bilateral uptake	Unilateral	None

ACTH, adrenocorticotropic hormone.

between the various etiologies requires a careful history and pertinent laboratory work (Table 85–2).

The remaining 20% of Cushing's syndrome cases are ACTH-independent and divided almost equally between adrenal adenomas and adrenal carcinomas, with rare cases caused by macronodular hyperplasia, primary pigmented nodular adrenal disease, and McCune-Albright syndrome.[3,5] The majority of adrenal cortex tumors are benign adenomas. Adrenal carcinoma is found more often in children than in adults with Cushing's syndrome.

Clinical Presentation

Patients with Cushing's syndrome commonly present (>90% of patients) with central obesity and facial rounding. In addition, approximately 50% of patients will exhibit some peripheral obesity and fat accumulation. Fat accumulation in the dorsocervical area (buffalo hump) can be associated with any major weight gain, whereas increased supraclavicular fat pads are more specific for Cushing's syndrome. Striae usually are present along the lower abdomen and take on a red to purple color. Traditionally, hypertensive complications have been major contributors to the morbidity and mortality of Cushing's syndrome. Hypertension is diagnosed in 75% to 85% of patients, with diastolic blood pressures greater than 119 mm Hg noted in over 20% of patients.[6] In addition, glucose intolerance is present in 60% of patients. Thus, many patients meet diagnostic criteria for the metabolic syndrome and have a corresponding increased risk of CHD and stroke. Screening for Cushing's syndrome in this population and in patients with uncontrolled diabetes mellitus has been suggested,[7,8] particularly when these conditions surface at an unusually early age.[9]

CLINICAL CONTROVERSY

Traditionally, obesity was used as screening tool because of its high prevalence in Cushing's syndrome. However, given the current epidemic of obesity, routine screening in all overweight and obese individuals may result in a high rate of false-positive tests.

Diagnosis

2 The diagnosis of Cushing's syndrome involves two steps: (1) establishing the presence of hypercortisolism, which is relatively easy; and (2) differentiating between etiologies, which can be challenging (Fig. 85–4).[5,8,10] The presence of hypercortisolism can be established via the following tests: 24-hour urinary free cortisol (UFC), midnight plasma cortisol, late-night salivary cortisol, and/or the low-dose dexamethosone suppression test (DST) (using 1 mg dexamethasone for the overnight test or 0.5 mg/6 h for the classic 2-day study). However, because these tests cannot determine the etiology of Cushing's syndrome, other tests and procedures will be subsequently employed. Such tests can include any of the following: plasma ACTH via IRMA or RIA; adrenal vein catheterization; metyrapone stimulation test; adrenal, chest, or abdominal CT; CRH stimulation test; IPSS; JVS; cavernous sinus sampling; and pituitary MRI. High-dose DST has been used in the past, but is no longer recommended due to its poor specificity and limited diagnostic value. Other possible tests and procedures include insulin-induced hypoglycemia, somatostatin receptor scintigraphy, the desmopressin stimulation test, the naloxone CRH stimulation test, the loperamide test, the hexarelin stimulation test, and radionuclide imaging.[5,6,8,10–15] Table 85–3 summarizes some of the tests used to diagnose Cushing's syndrome.

Elevated UFC concentrations are highly suggestive of Cushing's syndrome, especially values fourfold greater than the upper limit of normal.[3,12] In contrast to plasma measurements of cortisol, UFC measures only unbound cortisol. Consequently, the UFC test is unaffected by conditions and medications that alter CBG levels. Normal reference values for UFC are 20 to 90 mcg per 24-hour period. A two- to threefold increase in urine cortisol is not uncommon in the patient with hyperfunction of the adrenal gland. Starvation, hydration from water loading (greater than 5 liters per day), alcoholism, and acute stress are all capable of elevating urine cortisol concentrations. Likewise, elevated UFC results can occur during therapy with topical steroids, carbamazepine, and fenofibrate depending on the type of UFC test. Conversely, renal impairment (CrCL of less than 60 mL/min) can falsely lower UFC concentrations. Because other pathologic conditions can increase the amount of free cortisol, additional tests may be warranted to confirm the diagnosis, or the diagnostic evaluation should be repeated when the acute stress has resolved. Of all urinary measures, UFC is the most useful assessment for patients with suspected Cushing's syndrome.[8,12,14]

CLINICAL PRESENTATION: CUSHING'S SYNDROME

General

- The most common findings, which are present in 90% of patients, are central obesity and facial rounding.

Symptoms

- Approximately 65% and 58% of patients complain of myopathies and muscular weakness, respectively.

Signs

- Peripheral obesity and fat accumulation is found in 50% of patients.
- Facial plethora is caused by an underlying atrophy of the skin and connective tissue and is seen in approximately 84% of patients.
- Patients often are described as having moon faces with a buffalo hump.
- Hypertension is seen in 75% to 85% of patients.

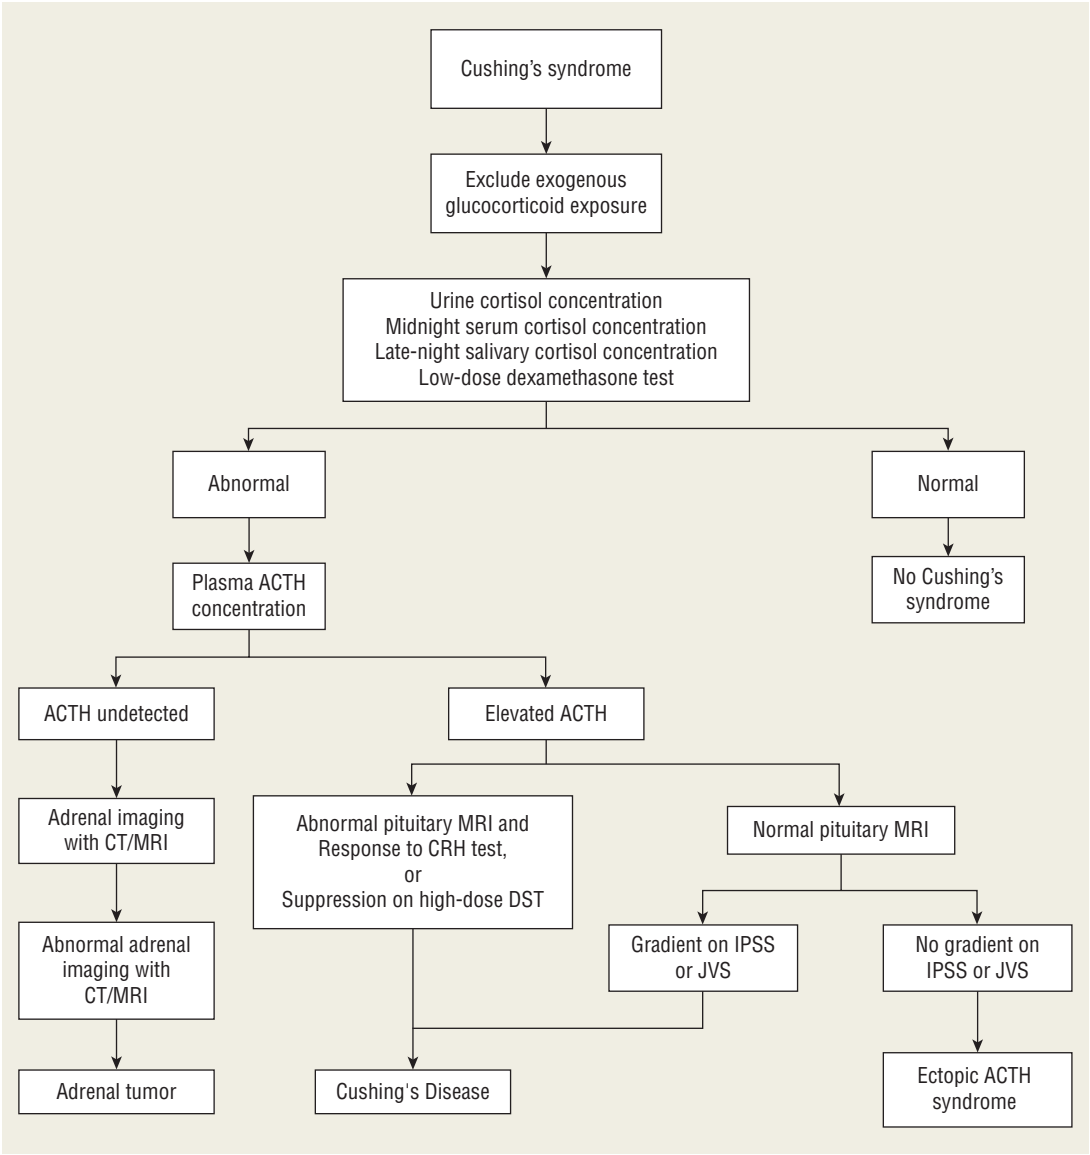

FIGURE 85-4. Algorithm for diagnosing Cushing's syndrome. (ACTH, adrenocorticotropic hormone.)

- Psychiatric changes can occur in as many as 55% of patients.
- Approximately 50% to 60% of patients will develop Cushing-induced osteoporosis. Of these, 40% will present with back pain and 20% will progress to compression fractures of the spine.
- Gonadal dysfunction is common with amenorrhea seen in up to 75% of females.
- Excess adrenal and ovary androgen secretion is responsible for 80% of females presenting with hirsutism.

Laboratory Tests

- A midnight plasma cortisol, late-night salivary cortisol, 24-hour UFC, and/or low-dose DST will establish the presence of hypercortisolism.

Other Diagnostic Tests

- The plasma ACTH test, metyrapone stimulation test, CRH stimulation test, or inferior petrosal sinus sampling will help determine the etiology.

TABLE 85-3 Summary of Tests Used to Diagnose Cushing's Syndrome

Test	Normal	Hyperplasia	Adenoma	Carcinoma
Plasma				
Cortisol (mcg/dL, AM/PM)	5–25/5–15	↑/↑↑	↑↑/↑↑	↑↑↑/↑↑↑
After low-dose DST	↓	↔	↔	↔
After high-dose DST	↓	↓/↔	↔	↔
ACTH (pg/mL)	6–76	↑↑	↓	↓
Urine				
Cortisol (mcg/24 h)	20–90	↑↑	↑↑	↑↑↑
Saliva				
Cortisol (mcg/dL, PM)	Assay-dependent	↑↑	↑↑	↑↑↑

ACTH, adrenocorticotropic hormone; DST, dexamethasone suppression test.

From Kratz A, Ferraro M, Sluss PM, Lewandrowski KB. Laboratory reference values. N Engl J Med 2004;351(15):1548–1563. Copyright © 2004 Massachusetts Medical Society. All rights reserved.

In healthy individuals, cortisol release follows a circadian rhythm whereby serum cortisol levels peak around 8:00 AM and thereafter decline by 60% to 80%, reaching a nadir between 3:00 and 4:00 AM. This rhythm is lost in the Cushing's syndrome patient. Although many patients with Cushing's syndrome will have serum cortisol values in the high normal range if the serum is assayed in the morning, only 3.4% will have normal values if measured late at night.[16] Thus, a midnight serum cortisol greater than 7.5 mcg/dL (>1.8 mcg/dL if the patient is sleeping) is a highly sensitive assay for Cushing's syndrome. However, this test is cumbersome and rarely recommended because it requires that patients be admitted for more than 48 hours to avoid false-positive responses secondary to the stress of hospitalization. An alternative assay is the measurement of late-night salivary cortisol. Salivary cortisol is highly correlated with free serum cortisol and independent of salivary flow rates. Moreover, salivary cortisol concentrations reflect changes in serum cortisol within minutes. Salivary cortisol can be considered as an acceptable alternative to UFC because of its convenience, stability (one week), accuracy, and reproducibility. Unfortunately, normal reference ranges are assay-dependent, and cutoff points vary among institutions.[17,18]

In the overnight DST, 1 mg of dexamethasone is administered at 11:00 PM. The following morning at 8:00 AM fasting plasma cortisol is obtained for analysis. This supraphysiologic dose suppresses ACTH stimulation and cortisol production in healthy individuals. In contrast, the negative feedback loop is ineffective in patients with Cushing's syndrome who generally exhibit morning cortisol concentrations above 5 mcg/dL. Some patients with Cushing's symdrome administered the overnight DST can slightly suppress cortisol and using 1.8 mcg/dL as a cutoff can increase sensitivity, but at the expense of reduced specificity.[19] Therefore, the overnight DST is useful only as a screening tool for Cushing's syndrome. Drugs that induce or inhibit CYP3A4 metabolism can significantly alter dexamethasone levels, increasing the number of false-positive and false-negative DST tests. Concurrent measurements of dexamethasone levels with cortisol may improve the accuracy of testing for patients on CYP3A4 modifying drugs, although dexamethasone assays are not widely available. Also noteworthy, pregnancy and estrogen use (including oral contraceptives) increase CBG levels and frequently illicit false-positive results.[12] Consequently, UFC testing is preferred over DST in these patient populations.

The first test used to determine the etiology of Cushing's syndrome is the plasma ACTH test. Plasma ACTH concentrations can be measured via RIA or IRMA.[11] In ACTH-dependent Cushing's syndrome, ACTH can be normal or elevated. Very high levels of ACTH favor ectopic production. In contrast, ACTH values generally are low (less than 5 pg/mL) in ACTH-independent (adrenal) Cushing's syndrome. Furthermore, ACTH levels can appear artificially low in some ectopic ACTH-producing tumors because ACTH can be secreted as an active prohormone that is not detected by the assay.

IPSS offers the highest sensitivity and specificity of any test in differentiating the etiology of Cushing's syndrome. This technique requires catheterization of both petrosal sinuses with serial measurements of ACTH in each sinus and a peripheral vein after administration of CRH. A central-to-peripheral ACTH gradient is diagnostic for Cushing's disease whereas no gradient indicates ectopic ACTH production. Complications, such as venous thromboembolism, brain stem vascular damage, cost, and technical expertise can limit use of this test.[11] JVS uses the same concept as IPSS, is less invasive, and produces fewer complications; however, sensitivity is compromised.

Abnormal adrenal anatomy is effectively identified using high-resolution CT scanning and MRI.[20] Nodules as small as 1 to 1.5 cm on the adrenal cortex are easily identified by CT. With the use of thin-section scanning, nodules as small as 3 to 5 mm can be visualized.[21] Importantly, adrenal incendentalomas are prevalent in 5% to 10% of the general population. These masses may be functional (secreting), requiring intervention, or nonfunctional (nonsecreting), requiring only periodic observation. For this reason, abnormal imaging results are unable to conclusively diagnose adrenal disease when used alone. Non-adrenal imaging studies may be useful for identifying ectopic sources of ACTH secretion in patients for whom IPSS has ruled out Cushing's disease.

Differential Diagnosis

Iatrogenic (exogenous) Cushing's syndrome is the most common form of the disease. Therefore, all patients exhibiting hypercortisolism should undergo a comprehensive history and evaluation assessing medication use before laboratory testing is performed to identify endogenous causes. Iatrogenic Cushing's syndrome can occur from administration of oral, inhaled, intranasal, intra-articular, and topical glucocorticoids, as well as progestins such as medroxyprogesterone acetate and megestrol acetate.[22] Disease severity correlates with exogenous glucocorticoid potency, dose, frequency, route, and treatment duration. Moreover, patients taking CYP3A4 inhibitors concomitantly with a glucocorticoid can be at higher risk of developing iatrogenic Cushing's syndrome.[23,24] If exogenous glucocorticoids are being taken, plasma cortisol levels can increase, while corticosterone levels remain low.[16]

In the absence of any known exogenous causes, the clinician will need to differentiate the syndrome from other syndromes, such as Pseudo-Cushing's syndrome, that mimic Cushing. Patients with obesity, chronic alcoholism, depression, and acute illness of any type can present with certain features of Cushing's syndrome. However, these patients may lack true Cushing's syndrome. For example, depressed patients, although mimicking the urinary steroid abnormalities of Cushing's syndrome, will not resemble a cushingoid patient in appearance. In chronic alcoholics, steroid laboratory panels generally return to baseline after ceasing alcohol intake. And obese patients often will have normal cortisol concentrations on both serum and urinary screening. Thus, identifying true cases of Cushing's syndrome requires a comprehensive history in combination with laboratory and possibly imaging assessment.

TREATMENT

3 If left untreated, Cushing's syndrome is associated with high morbidity and mortality owing to associated disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities. These disorders limit the survival of the patient with Cushing's syndrome to 4 to 5 years following initial diagnosis. The desired outcomes of treatment are to limit such detrimental outcomes and return the patient to a normal functional state by removing the source of hypercortisolism without causing any pituitary or adrenal deficiencies.

4 The treatment of choice for both ACTH-dependent and ACTH-independent Cushing's syndrome is surgical resection of any offending tumors.[3,10] However, several secondary pharmacologic treatment plans are available, depending on the etiology of the disease (Table 85–4).[25,26] These pharmacologic options are generally used in preoperative patients or as adjunctive therapy in postoperative patients awaiting response. Rarely, monotherapy is used as a palliative treatment when surgery is not indicated.

PHARMACOLOGIC THERAPY

5 Pharmacotherapy of Cushing's syndrome (dosing can be found in Table 85–4)[27] can be divided into four categories based on the anatomic site of action of the agent: (1) steroidogenesis inhibitors,

TABLE 85-4 Possible Treatment Plans in Cushing's Syndrome Based on Etiology

	Treatment				
			Dosing		
Etiology	*Nondrug*	*Generic (Brand) Drug Name*	*Initial*	*Usual*	*Max*
Ectopic ACTH syndrome	Surgery, chemotherapy, irradiation	Metyrapone (Metopirone) 250-mg capsules	0.5–1 g/day, divided every 4–6 h	1–2 g/day, divided every 4–6 h	6 g/day
		Aminoglutethimide (Cytadren) 250-mg tabs	0.5–1 g/day, divided two to four times a day for 2 weeks	1 g/day, divided every 6 h	2 g/day
Pituitary-dependent	Surgery, irradiation	Cyproheptadine (Periactin) 2 mg/5 mL syrup or 4-mg tabs	4 mg twice a day	24–32 mg/day, divided four times a day	32 mg/day
		Mitotane (Lysodren) 500-mg tabs	0.5–1 g/day, increased by 0.5–1 g/day every 1–4 weeks	1–4 g daily, with food to decrease GI effects	12 g/day
		Metyrapone	See above	See above	See above
Adrenal adenoma	Surgery, postoperative replacement	Ketoconazole (Nizoral) 200-mg tabs	200 mg once or twice a day	200–1200 mg/day, divided twice a day	1600 mg/day divided four times a day
Adrenal carcinoma	Surgery	Mitotane	See above	See above	See above

ACTH, adrenocorticotropic hormone.

(2) adrenolytic agents, (3) neuromodulators of ACTH release, and (4) glucocorticoid-receptor blocking agents.[25,26]

Steroidogenesis Inhibitors

As their name implies, steroidogenesis inhibitors block the production of cortisol. This class includes metyrapone, ketoconazole, etomidate, and aminoglutethimide. Metyrapone inhibits 11β-hydroxylase, the enzyme responsible for converting 11-deoxycortisol to cortisol. Following administration, a sudden decrease in cortisol levels occurs within hours and prompts a compensatory rise in plasma ACTH concentrations. As ACTH increases and blockage of cortisol synthesis persists, adrenal steroidogenesis efforts are shunted toward androgen production. Consequently, metyrapone is associated with significant androgenic side effects, including hirsutism and increased acne. In addition, metyrapone blocks aldosterone synthesis and causes the accumulation of aldosterone precursors, which exhibit weak mineralocorticoid activity. Blood pressure and electrolyte level variations can ensue, depending on the level of circulating 11-deoxycortisol and the degree of aldosterone inhibition. Additional adverse effects, including nausea, vomiting, vertigo, headache, dizziness, abdominal discomfort, and allergic rash, have been reported following administration, but are often signs of overtreatment.[25,26,28] Metyrapone is currently available through the manufacturer only for compassionate use.

The imidazole derivative antifungal, ketoconazole, effectively inhibits steroidogenesis via multiple mechanisms when used in large doses. In contrast to the quick onset of metyrapone, the benefits of ketoconazole therapy are achieved only after several weeks of therapy. In addition to lowering serum cortisol levels, ketoconazole exhibits anti-androgenic activity attributable to its inhibition of multiple CYP enzymes as well as 11β-hydroxylase and 17α-hydroxylase.[25] This activity may be beneficial in female patients with Cushing's syndrome, but can cause gynecomastia and decreased libido in males. Sustained therapy with ketoconazole also imparts beneficial effects on serum cholesterol profiles, including lowering total and LDL cholesterol levels. Ketoconazole induces a reversible elevation of hepatic transaminases in approximately 10% of patients.[29] Frequent liver function monitoring is recommended although progression to serious hepatotoxicity is rare. Additional common adverse effects include gastrointestinal discomfort and dermatologic reactions.

Ketoconazole may be used concomitantly with metyrapone to achieve synergistic reductions in cortisol levels. Because these drugs differ in their onset of action, coadministration allows for more complete suppression of cortisol synthesis. Moreover, the anti-androgenic actions of ketoconazole therapy may offset the androgenic potential of metyrapone, thus attenuating a major limitation of metyrapone therapy.

The anesthetic etomidate is an imidazole derivative similar to ketoconazole that inhibits 11β-hydroxylase.[25] Etomidate is available only in a parenteral formulation and is therefore limited to patients with acute hypercortisolemia requiring emergency treatment.

Initially, aminoglutethimide was used to treat refractory forms of epilepsy, but was later discovered to be a potent inhibitor of adrenal steroid synthesis. Aminoglutethimide inhibits the conversion of cholesterol to pregnenolone early in the steroid biosynthesis pathway, thereby inhibiting the production of cortisol, aldosterone, and androgens. Owing to these broad inhibitory actions, side effects, including severe sedation, nausea, ataxia, and skin rashes, limit the use of aminoglutethimide in many patients.[25,26] Moreover, because other steroidogenesis inhibitors offer greater efficacy combined with fewer side effects, aminoglutethimide has fallen out of favor in the treatment of Cushing's syndrome. If aminoglutethimide is used, it should be coadministered with another steroidogenesis inhibitor, usually metyrapone, secondary to high relapse rates with aminoglutethimide monotherapy.

Adrenolytic Agents

Mitotane is a cytotoxic drug that structurally resembles the insecticide dichlorodiphenyltrichloroethane (DDT). Mitotane inhibits the 11-hydroxylation of 11-desoxycortisol and 11-desoxycorticosterone in the cortex, resulting in a net inhibition of cortisol and corticosterone synthesis. Similar to ketoconazole, mitotane takes weeks to months to exert beneficial effects. Sustained cortisol suppression occurs in most patients and may persist following discontinuation of therapy in up to one third of patients. Because of its cytotoxic nature, mitotane degenerates cells within the zona fasciculata and reticularis, resulting in atrophy of the adrenal cortex. The zona glomerulosa is minimally affected during acute therapy but can become damaged following long-term treatment.[27,30]

Importantly, mitotane can induce significant neurological and gastrointestinal side effects and patients should be monitored carefully or hospitalized when initiating therapy. Nausea and diarrhea are common adverse effects that occur at doses greater than 2 g/day and can be avoided by gradually increasing the dose and/or administering the agent with food. Approximately 80% of patients treated with mitotane develop lethargy and somnolence, and other central nervous system adverse drug reactions occur in approximately 40% of patients. Furthermore, significant but reversible hypercholesterolemia and prolongation of bleeding times can result

from mitotane use.[25,26] Mitotane increases production of corticosteroid binding globulin resulting in elevated plasma cortisol; thus, UFC and urinary steroid production should be monitored to assess response to therapy.[25] If necessary, steroid replacement therapy can be given. However, because mitotane also increases extraadrenal metabolism of exogenously administered corticosteroids, higher steroid replacement doses may be required.

Neuromodulatory Agents

Pituitary secretion of ACTH is normally mediated by various neurotransmitters, including serotonin, GABA, acetylcholine and the catecholamines. Although ACTH-secreting pituitary tumors (Cushing's disease) self-regulate ACTH production to some degree, these neurotransmitters are still capable of promoting pituitary ACTH production. Consequently, agents that target these neurotransmitters have been proposed for the treatment of Cushing's disease. Such agents include cyproheptadine, ritanserin, ketanserin, bromocriptine, cabergoline, valproic acid, octreotide, lanreotide, rosiglitazone, and tretinoin. However, none of these drugs have demonstrated consistent clinical efficacy in the treatment of Cushing's disease.

Cyproheptadine, a nonselective serotonin receptor antagonist and anticholinergic drug, can decrease ACTH secretion in some Cushing's disease patients. However, side effects, including sedation and weight gain, significantly limit the use of this drug. Likewise, selective serotonin type 2 receptor antagonists, including ritanserin and ketanserin, have demonstrated limited efficacy. Owing to their poor efficacy and high relapse rates, these drugs should be avoided except in nonsurgical candidates refractory to more conventional treatments.

Dopamine D_2 receptor agonists, including bromocriptine and cabergoline, initially reduce ACTH secretion in as many as half of all patients with Cushing's disease. This action occurs through activation of inhibitory D_2 receptors that are expressed in approximately 80% of pituitary adenomas.[31] Reductions in ACTH levels are often minor and rarely sustained with long-term bromocriptine therapy. Cabergoline exhibits a higher specificity and affinity for D_2 receptors as well as a prolonged half-life compared with bromocriptine, but long-term studies for cabergoline are lacking.

The somatostatin analogues, octreotide and lanreotide, generally are ineffective in reducing ACTH secretion in Cushing's disease. These two agents primarily target somatostatin receptor subtype 2 (sst_2), whereas pituitary adenomas predominantly express sst_5. Pasireotide, an investigational somatostatin analogue, exhibits a high affinity for both sst_2 and sst_5 and may show promise as a future treatment in Cushing's disease.

Glucocorticoid-Receptor Blocking Agents

Mifepristone (RU-486) is a potent progesterone- and glucocorticoid-receptor antagonist that inhibits dexamethasone suppression and increases endogenous cortisol and ACTH levels in normal subjects.[25,28] Limited clinical experience in Cushing's syndrome suggests that mifepristone is highly effective in reversing the manifestation of hypercortisolism. Though because of its novel site of action, mifepristone induces a compensatory rise in ACTH and cortisol levels. Consequently, efficacy and toxicity monitoring must rely on clinical signs rather than laboratory assessments. Given these monitoring challenges, mifepristone use remains investigational for the treatment of Cushing's syndrome.

Close monitoring of 24-hour UFC levels and serum cortisol levels are essential to detect treatment-induced adrenal insufficiency. Steroid secretion should be monitored with all of these drugs and steroid replacement given as needed. Whatever the choice, pharmacologic therapy in pituitary-dependent disease is mainly centered around patient stabilization prior to surgery or in patients waiting for potential response to other therapies.

NONPHARMACOLOGIC THERAPY

Surgery

The treatment of choice for Cushing's disease is transsphenoidal resection of the pituitary microadenoma.[3,10,28,32] The advantages of this procedure include preservation of pituitary function, low complication rate, and high clinical improvement rate. The overall cure rate of histologically proven microadenomas approaches 90%, whereas remission rates for macroadenomas generally do not exceed 65%.

For persistent disease following transsphenoidal surgery or when tumor-specific surgery is not possible, several second-line treatment options are available and should be tailored toward the individual patient. In the case of persistent disease following transsphenoidal surgery, repeat surgery may be performed, although overall remission rates are lower with subsequent procedures. Alternatively, radiotherapy may be preferred for tumors invading the dura or cavernous sinus because these tumors respond poorly to surgical intervention.[33] Radiotherapy provides clinical improvement in approximately 50% of patients within 3 to 5 years, but increases the risk for pituitary-dependent hormone deficiencies (hypopituitarism).

Laparoscopic adrenalectomy is often preferred in patients with unilateral adrenal adenomas for whom transsphenoidal surgery and pituitary radiotherapy have failed or cannot be used.[3,10,28] Bilateral adrenalectomy rapidly reverses hypercortisolism. However, patients can develop Nelson syndrome, an aggressive pituitary tumor that secretes high quantities of ACTH, which causes hyperpigmentation. Because Nelson syndrome occurs in as many as 30% of bilateral adrenalectomy cases, patients should undergo regular MRI scans and ACTH level assessments. Additionally, these patients require lifelong glucocorticoid and mineralocorticoid supplementation.

Adrenal Adenoma

Surgical resection of benign adrenal adenoma is associated with relatively few side effects and a high cure rate (95%). The contralateral gland in the patient with adrenal adenoma is usually atrophic, therefore steroid replacement is needed both perioperatively and postoperatively. Table 85–5 outlines an approach to steroid replacement for three separate routes of hydrocortisone. Therapy should be continued for 6 to 12 months following surgery. Before replacement therapy is discontinued, recovery of the adrenal axis can be assessed by measuring the morning (8 AM) cortisol level. Cortisol levels should exceed 20 mcg/dL before discontinuing exogenous steroids.[22]

TABLE 85-5 Alternative Steroid Replacement Regimens in the Adrenal Adenoma Patient

	Hydrocortisone Dose (mg)		
Time	***IV***	***IM***	***PO***
Operation day	300	50 before surgery and 50 after surgery	
Postoperative day 1	200	50 every 12 h	
Postoperative day 2	150	50 every 12 h	
Postoperative day 3	100	50 every 12 h	
Postoperative day 4		50 every 12 h	25 every 6 h
Postoperative day 5		25 every 12 h	25 every 6 h[a]
Postoperative day 7			25 every 6 h
Postoperative days 8–10			25 every 8 h
Postoperative days 11–20			25 every 12 h
Postoperative days 21+			20 at 8 AM 10 at 4 PM

PO, orally.
[a]Add fludrocortisone 0.05–2 mg orally once daily starting on postoperative day 5. Adjust dose based on blood pressure, body weight, and serum electrolytes.

Adrenal Carcinoma

Unlike the benign adenoma patient, those with adrenal carcinoma have an unfavorable outcome with surgical resection.[10] Often the complete tumor cannot be excised, leaving the patient with some degree of symptomatology and extraadrenal involvement. Radiotherapy can be used if metastases are discovered. In the patient with adrenal carcinoma who is not a surgical candidate, the focus of treatment is on palliative pharmacologic intervention.

Mitotane may be used in inoperable functional and nonfunctional adrenal carcinoma or as adjuvant therapy in surgical patients with a high risk of relapse. However, mitotane induces tumor regression in less than 20% of patients.[34] Metyrapone, aminoglutethimide, and ketoconazole can be given to attempt control of steroid hypersecretion. 5-fluorouracil also has been used in combination therapy.

Ectopic ACTH Syndrome

In ectopic ACTH syndrome, ACTH-secreting tumors may exist in a variety of sites, including thymic, pulmonary, appendiceal, pancreatic, and thyroid tissues. Locating these sites is often difficult, but essential for determining an appropriate treatment strategy. Surgical resection is the most effective treatment option for these patients, but only approximately 10% to 30% of patients are cured following surgery due to high rates of metastatic disease or occult tumors. The remaining 70% to 90% receive postoperative medication.

Pharmacologic management with steroidogenesis inhibitors is effective in ectopic ACTH syndrome. Mitotane has been used in patients with ectopic ACTH syndrome; however, its side-effect profile generally limits its use. Mifapristone and somatostatin analogs also have been reported to reduce the clinical signs of ectopic ACTH syndrome.[35]

Additional tumor-directed therapy can include systemic chemotherapy, interferon α, chemoembolization, radiofrequency ablation, and radiation therapy.[33] If all else fails, bilateral adrenalectomy can prevent the downstream effects (e.g., steroidogenesis) of high levels of tumor ACTH secretion.

HYPERALDOSTERONISM

Excess aldosterone secretion is categorized as either primary or secondary hyperaldosteronism.[36–40] In primary aldosteronism (PA), the stimulation for aldosterone secretion arises from within the adrenal gland. Conversely, extraadrenal stimulation is classified as secondary aldosteronism.

Primary Aldosteronism

Etiology The most common causes of PA include BAH (65%) and aldosterone-producing adenoma (APA; otherwise known as Conn syndrome) (30%). Other rare causes include unilateral (primary) adrenal hyperplasia, adrenal cortex carcinoma, renin-responsive adrenocortical adenoma, and two forms of familial hyperaldosteronism (FH): FH type 1, or glucocorticoid-remediable aldosteronism (GRA) and FH type II.[36,37,39]

Clinical Presentation PA is present in approximately 10% of the general hypertensive population and is the leading cause of secondary hypertension. The disease is more common in women than men and diagnosis usually occurs between the third and sixth decade of life. Signs and symptoms can include arterial hypertension, which is often moderate to severe and resistant to pharmacologic intervention, as well as hypokalemia (10% to 40% of PA patients), muscle weakness, fatigue, and headache. These features are non-specific for PA and many patients are asymptomatic. Historically, hypokalemia was considered a requisite feature for PA diagnosis; however, normokalemia exists frequently in patients and should not obviate concern for PA.

TABLE 85-6 Differential Diagnosis of Primary Aldosteronism

Disease	Plasma Renin Concentration	Plasma Aldosterone Concentration	Blood Pressure
Primary aldosteronism	Low	High	High
Edematous disorders	High	High	Normal
Malignant hypertension	High	High	High
Congenital adrenal hyperplasia	Low	Low	High
Cushing's syndrome	Low to normal	Low to normal	High
Liddle syndrome	Low	Low	High
Bartter's syndrome	High	High	Low to normal
Licorice ingestion	Low	Low	High
Low-renin essential hypertension	Low	Low to normal	High

Diagnosis Diagnostic confirmation of PA is obtainable through screening, confirmatory tests, and subtype differentiation. As in Cushing's syndrome, discovery of the underlying etiology ensures proper treatment. Table 85–6 lists the various abnormalities that must be ruled out when suspicion of hyperaldosteronism is high.

CLINICAL PRESENTATION: PRIMARY ALDOSTERONISM

Symptoms

- Patients may complain of muscle weakness, fatigue, paresthesias, and headache.

Signs

- Hypertension
- Tetany/paralysis
- Polydipsia/nocturnal polyuria

Laboratory Tests

- A plasma-aldosterone–to–plasma-renin-activity ratio (PA:PRA), or aldosterone-to-renin ratio (ARR) greater than 20 is suggestive of primary aldosteronism
- Common laboratory findings include suppressed renin activity, elevated plasma aldosterone concentrations, hypernatremia (>142 mEq/L), hypokalemia, hypomagnesemia, elevated bicarbonate concentration (>31 mEq/L), and glucose intolerance

Confirmatory Tests

- Oral or intravenous saline loading, fludrocortisone suppression test (FST), and genetic testing

Initial diagnosis is made through proper screening of patients with suspected primary aldosteronism. Such patients include those with JNC stage two hypertension—appreciating that the prevalence of PA increases with hypertensive severity—and resistant hypertensives. Screening for primary aldosteronism is most often done by using the plasma-aldosterone-concentration–to–plasma-renin-activity ratio (PAC:PRA), otherwise known as the aldosterone-to-renin ratio (ARR). An elevated ARR is highly suggestive of PA; however, an optimal cutoff level remains undefined because testing conditions (posture, time, current drug therapy, recent dietary salt intake), patient characteristics, and variable levels of specificity and sensitivity among assays can significantly alter test results.[41] ARR cutoffs of 20 to 40 or 20 with an aldosterone level greater than 15 ng/dL are used most often.[38,42,43]

Following a positive ARR screening test, confirmatory testing must be performed to exclude any false-positive cases. Confirmatory tests include the oral sodium loading test, saline infusion test, FST, and the captopril challenge test. Although individual tests can vary in sensitivity, specificity and reliability, any test can be used depending on patient- and institution-specific considerations. FST generally is considered the most reliable, but requires hospitalization. Prior to performing these tests, potassium levels must be normalized and RAS-active agents should be temporarily discontinued, if possible. Positive tests indicate autonomous aldosterone secretion under inhibitory pressures and are diagnostic for PA. After diagnosis, patients with confirmed PA before age 20 or with a family history of PA or strokes before age 40 should undergo genetic testing to properly identify GRA.[41]

Differentiating between an APA and BAH is imperative to formulate a proper treatment plan. Most adenomas are singular and small (<1 cm) and occur more often in the left adrenal gland than the right. Patients with APA generally have more severe hypertension, more profound hypokalemia, and higher plasma and urinary aldosterone levels compared with patients with BAH. Adrenal venous sampling (AVS) provides the most accurate means of differentiating unilateral from bilateral forms of PA. However, AVS is expensive, invasive, and frequently unavailable. CT scanning can detect most adenomas, although an incidentaloma can occasionally cause confusion. If CT scanning is inconclusive, AVS is performed to characterize lateralization.[38,44–46]

The underlying abnormality in BAH remains a mystery, but some investigators believe that a hormone factor stimulates the zona glomerulosa, resulting in increased sensitivity to angiotensin II. In contrast to those with an APA, patients with BAH are able to maintain control of the renin-angiotensin system, with little effect following doses of ACTH.

Therapeutic Management

6 ***BAH-Dependent Aldosteronism.*** Aldosterone receptor antagonists are the treatment of choice in bilateral cases of primary aldosteronism. Spironolactone, a non-selective aldosterone receptor antagonist, competes with aldosterone for binding at the aldosterone receptor, thus preventing the negative downstream effects of aldosterone receptor activation. Additionally, spironolactone is capable of inhibiting aldosterone synthesis within the adrenal gland; however, the magnitude of this inhibition is relatively small and the effect only occurs at doses above those achieved with therapeutic doses.[47] Spironolactone is available in oral form, with most patients responding to doses between 25 and 400 mg/day. The clinician should wait 4 to 8 weeks before reassessing the patient for urinary electrolytes and blood pressure control. Adverse effects of spironolactone are dose-dependent and include gastrointestinal discomfort, impotence, gynecomastia, menstrual irregularities, and hyperkalemia. Gynecomastia and menstrual irregularities observed with spironolactone therapy arise from activity at androgen and progesterone receptors and inhibition of testosterone biosynthesis. Additionally, because salicylates increase the renal secretion of canrenone, the active metabolite, patients should be advised to avoid concomitant therapy with salicylates. In patients intolerant of spironolactone, alternative options include eplerenone and amiloride.[38,48–50]

Eplerenone is a selective aldosterone receptor antagonist with high affinity for the aldosterone receptor and low affinity for androgen and progesterone receptors. Consequently, eplerenone elicits fewer sex steroid-dependent effects while ostensibly maintaining similar efficacy to spironolactone; however, no significant comparative data exist between these two agents. Dosing starts at 50 mg daily, with titration to 50 mg twice a day.[48] Titration should occur at 4 to 8 week intervals. In addition, eplerenone is a substrate of CYP3A4 and should not be taken with potent CYP3A4 inhibitors. Eplerenone has been proven effective in primary essential hypertension; however, its role in the management of hyperaldosteronism has not been established.[51]

Amiloride, a potassium-sparing diuretic, is dosed at 5 mg twice a day up to 30 mg/day if necessary. Amiloride is less effective than spironolactone and often requires additional therapy to adequately control blood pressure. Additional agents useful as second-line options include the calcium channel blockers, ACE inhibitors, and low-dose diuretics such as hydrochlorothiazide, although all lack outcome data evaluation in PA.[46,49]

Aldosterone synthase inhibitors, currently under development, may offer additional therapeutic options in the future.

APA-Dependent Aldosteronism. The treatment of choice for APA-dependent aldosteronism remains laparoscopic resection of the adenoma.[52] Nearly 100% of patients show blood pressure improvement while 30% to 72% are permanently cured.[50,53] Because APAs are small and often occur in multiples, resection should target the entire adrenal gland. In successful cases, blood pressure control is achieved in 1 to 3 months. Medical management can be efficacious in this population if surgery is contraindicated. However, medical management may be significantly more expensive than unilateral resection.

Glucocorticoid-Remediable Aldosteronism. Glucocorticoids are very effective in treating GRA.[37] Low doses are used (0.125 to 0.5 mg/day of dexamethasone or 2.5 to 5 mg/day of prednisone) because complete suppression of ACTH-stimulated aldosterone release is unnecessary. Spironolactone, eplerenone, and amiloride are alternative treatment options.[38]

Summary The diagnosis of PA is made through proper screening of suspected patients followed by confirmatory testing. Subsequent differentiation between the various etiologies ensures appropriate treatment (Fig. 85–5). Patients with APA can be distinguished from patients with BAH by CT scan, but adrenal venous sampling provides increased sensitivity and specificity. Treatment depends on the etiology with surgical resection in adenomas, and spironolactone, eplerenone, or amiloride plus second-line agents in patients with bilateral hyperplasia.

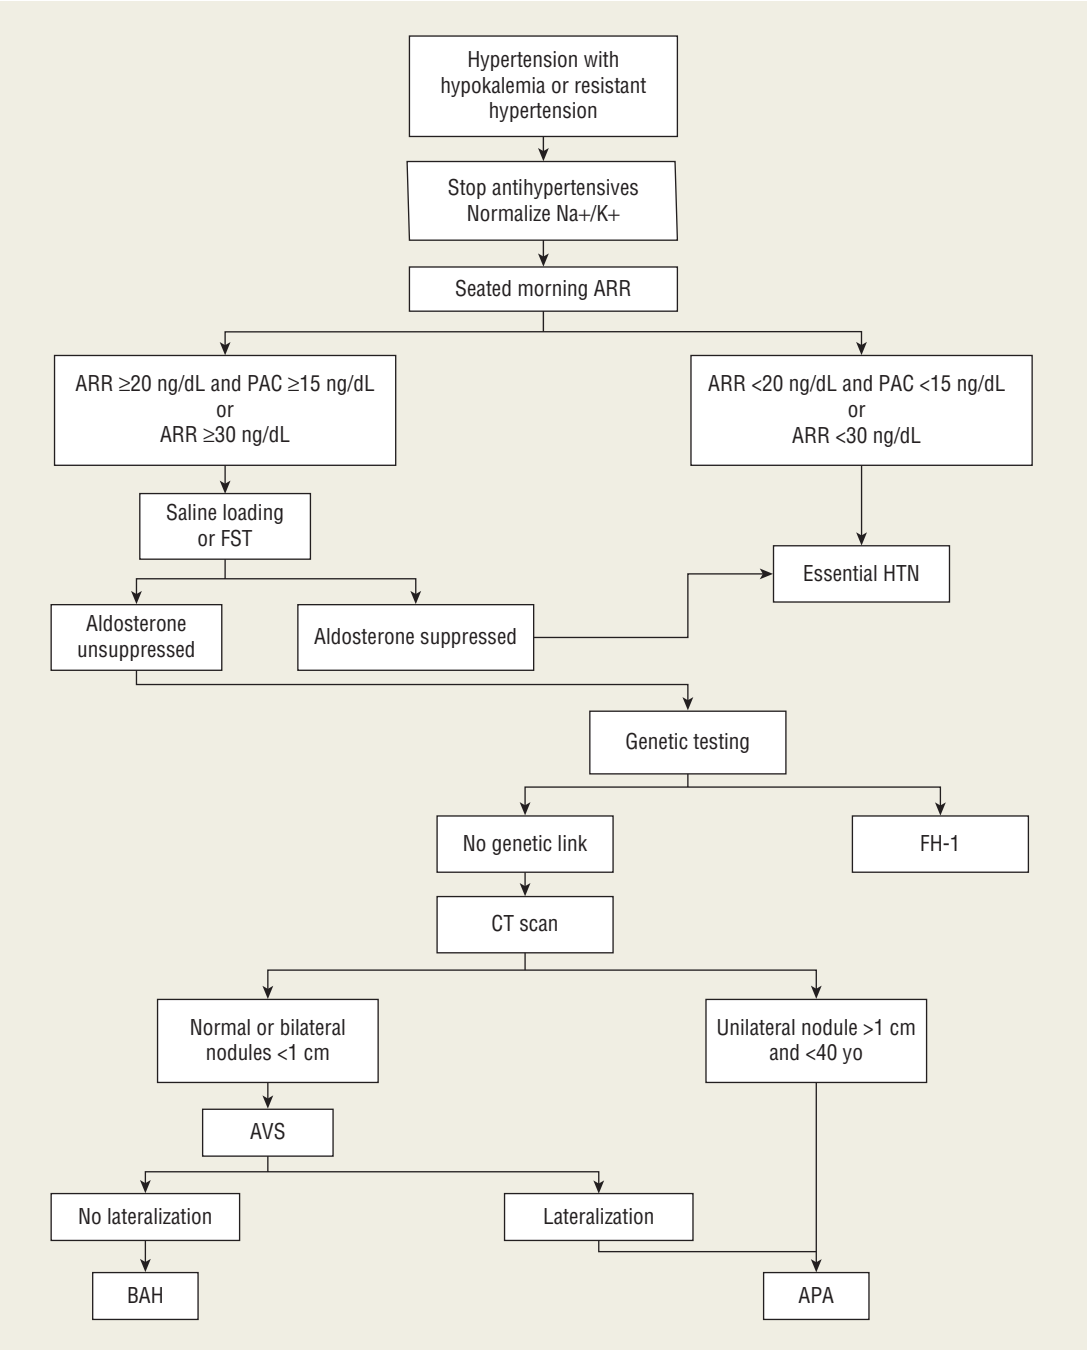
Secondary Aldosteronism

Secondary aldosteronism results from an appropriate response to excessive stimulation of the zona glomerulosa by an extraadrenal factor, usually the renin-angiotensin system. Excessive potassium intake can promote aldosterone secretion, as can oral contraceptive use, pregnancy (10 times normal by the third trimester), and menses. Congestive heart failure, cirrhosis, renal artery stenosis, and Bartter syndrome also can lead to elevated aldosterone concentrations.

Treatment of secondary aldosteronism is dictated by etiology. Control or correction of the extraadrenal stimulation of aldosterone secretion should resolve the disorder. Medical therapy with spironolactone is the mainstay of treatment until an exact etiology can be located.

HYPOFUNCTION OF THE ADRENAL GLAND

7 Primary adrenal insufficiency, or Addison's disease, most often involves the destruction of all regions of the adrenal cortex. Deficiencies arise in cortisol, aldosterone, and the various androgens and levels of CRH and ACTH increase in a compensatory manor. In developed countries, autoimmune dysfunction is responsible for most cases (80% to 90%), whereas tuberculosis predominates as



ARR = aldosterone to renin ratio
PAC = plasma aldosterone concentration
FST = fludrocortisone suppression test
FH-1 = familial hyperaldosteronism type 1
AVS = adrenal venous sampling
BAH = bilateral adrenal hyperplasia
APA = aldosterone-producing adenoma

FIGURE 85-5. Algorithm for the diagnosis of primary aldosteronism.

the cause in developing countries. Approximately 50% of patients with autoimmune etiologies present with one or more concomitant autoimmune disorders, usually involving other endocrine organs. Autoimmune thyroid disorders (e.g., Hashimoto's thyroiditis or Graves disease) are the most common, but the ovaries, pancreas, parathyroid gland and organs of the gastrointestinal system can also be affected. This polyglandular failure syndrome, termed autoimmune polyendocrine syndrome (APS), is associated with the idiopathic etiology only and has not been seen with adrenal insufficiency associated with tuberculosis or other invasive diseases. Medications that inhibit cortisol synthesis (ketoconazole), or accelerate cortisol metabolism (phenytoin, rifampin, phenobarbital) can also cause primary adrenal insufficiency.[54]

8 Secondary insufficiency is characterized by reduced glucocorticoid production secondary to decreased ACTH levels. Low levels of ACTH most commonly result from exogenous steroid use, leading to suppression of the HPA axis and decreased release of ACTH, resulting in impaired androgen and cortisol production. These effects occur with oral, inhaled, intranasal, and topical glucocorticoid administration.[55–57] Moreover, mirtazapine and progestins, such as medroxyprogesterone acetate and megestrol acetate, have been reported to induce secondary adrenal

TABLE 85-7 Etiologies of Primary and Secondary Adrenal Insufficiency

Primary Insufficiency	Secondary Insufficiency
Slow onset	Craniopharyngioma
Acquired immunodeficiency syndrome	Cure of Cushing's syndrome
Adrenomyeloneuropathy	Empty sella syndrome
Adrenoleukodystrophy	Tumors of the third ventricle
Amyloidosis	Histiocytosis
Autoimmune adrenalitis[a]	Hypothalamic tumors
Bilateral adrenalectomy	Hypopituitarism
Congenital adrenal hypoplasia	Long-term corticosteroid administration
Hemochromatosis	Lymphocytic hypophysitis
Isolated glucocorticoid deficiency	Pituitary surgery, radiation, or tumor
Metastatic neoplasia	Sarcoidosis
Systemic fungal, bacterial, or viral infections Tuberculosis[b]	Medications–progestins and glucocorticoid discontinuation
Medications–ketoconazole, etomidate, rifampin, phenytoin, phenobarbital	Postpartum pituitary necrosis
	Necrotic or bleeding pituitary macroadenoma
Fast onset	
Adrenal thrombosis, hemorrhage, sepsis, trauma, or necrosis	Head trauma, lesions of the pituitary stalk Pituitary or adrenal surgery for Cushing's syndrome

[a]Accounts for approximately 70% of cases.
[b]Accounts for approximately 20% of cases.

insufficiency.[58,59] Chronic suppression also can result in atrophy of the anterior pituitary and hypothalamus, impairing recovery of function if the exogenous steroid is reduced. Endogenous secondary insufficiency can occur with tumor development in the hypothalamic-pituitary region. Secondary disease classically presents with normal concentrations of mineralocorticoids since the zona glomerulosa is controlled by the renin-angiotensin system rather than ACTH levels.

Approximately 90% of the adrenal cortex must be destroyed before adrenal insufficiency symptoms will occur.[60] Specific etiologies for both primary and secondary insufficiency are listed in Table 85–7. Adrenal hemorrhage can result from multiple etiologies including traumatic shock, coagulopathies, ischemic disorders, and other situations of severe stress, but septicemia is the most common. Symptoms include truncal pain, fever, shaking, chills, hypotension preceding shock, anorexia, headache, vertigo, vomiting, rash, psychiatric symptoms, abdominal rigidity or rebound, and death in 6 to 48 hours if not treated. The most common organisms found on autopsy are *Neisseria meningitidis, Pseudomonas aeruginosa, Streptococcus pneumoniae*, Group A *Streptococcus*, and *Haemophilus influenzae*.[60,61]

ADDISON'S DISEASE

Distinguishing Addison's disease from secondary insufficiency is difficult; however, the following guidelines may be helpful:

1. Hyperpigmentation, commonly found in areas of skin exposed to increased friction, is seen only in Addison's disease because of excess secretion of ACTH and other proopiomelanocortin (POMC) peptides which induce melanocyte-stimulating hormone production. Secondary adrenal insufficiency is fundamentally characterized by deficient ACTH and POMC peptide secretion and a corresponding low level of melanocyte-stimulating hormone production. In fact, some patients with secondary insufficiency may exhibit pale-colored skin secondary to hypopigmentation.
2. Aldosterone secretion usually is preserved in secondary insufficiency.
3. Weight loss, dehydration, hyponatremia, hyperkalemia, and elevated blood urea nitrogen are common in Addison's disease.
4. Addison's disease will have an abnormal response to the short corticotropin-stimulation test. Plasma ACTH levels are usually 400 to 2000 pg/mL in primary insufficiency, versus low to normal (5 to 50 pg/mL; see Table 85–3) in secondary insufficiency. A normal corticotropin-stimulation test does not rule out secondary adrenal insufficiency, particularly in mild cases.

The short corticotropin-stimulation test, also known as the cosyntropin-stimulation test, can be used to assess patients suspected of hypocortisolism. Patients are given 250 mcg of synthetic ACTH intravenously or intramuscularly, with serum cortisol levels drawn at baseline and 30 to 60 minutes after the injection. A resulting cortisol level ≥18 mcg/dL (500 nmol/L) rules out adrenal insufficiency.[62] Because 250 mcg represents a massive supraphysiologic dose, this test can elicit normal, elevated cortisol responses in some cases of mild secondary insufficiency. Thus, some suggest that higher cutoff values (≥22 mcg/dL [≥600 nmol/L]) should be used to prevent false-negative test results.[63] Alternatively, a low-dose corticotropin-stimulation test, using 1 mcg of synethetic ACTH, can achieve equivalent results to the standard test and is more sensitive in establishing the diagnosis of secondary insufficiency.[64] Other tests include the insulin hypoglycemia test, the metyrapone test, and the corticotropin-releasing hormone stimulation test.[54,62,65]

The standard cutoffs described above are of limited use in acutely ill patients.[66] Severe infection, trauma, burns, illnesses, or surgery can increase cortisol production by as much as a factor of six, making the recognition of adrenal insufficiency in this population extremely difficult. In the critically ill, a random cortisol level below 15 mcg/dL (415 nmol/L) is suggestive of adrenal insufficiency, whereas a level greater than 34 mcg/dL (940 nmol/L) suggests that adrenal insufficiency is unlikely.[66] For patients who fall between these two values, a poor response to corticotropin (less than 9 mcg/dL [250 nmol/L] increase in plasma cortisol from baseline at 30 or 60 minutes) indicates the possibility of adrenal insufficiency and a need for corticosteroid supplementation.[66] A severe hypoproteinemic patient (albumin <2.5 g/L) will have markedly lower CBG, which can falsely underestimate the free fraction of cortisol. These patients can benefit from retesting as an outpatient to prevent indefinite glucocorticoid therapy.[54]

Treatment of Addison's disease must include adequate patient education, so that the patient is aware of treatment complications, expected outcome, consequences of missed doses, and drug side effects. The agents of choice are hydrocortisone, cortisone, and prednisone, administered twice daily with the treatment objective being the establishment of the lowest effective dose while mimicking the normal diurnal adrenal rhythm.[54] Usually a twice-daily dosing schedule is adequate with the dose depending on the agent used.

Endogenous cortisol production varies between 5 and 10 mg/m^2 per day.[67] Hence, the classic 12 to 15 mg/m^2 per day rule for cortisol supplementation can be excessive in most patients. Recommended starting doses to properly mimic endogenous cortisol production are 15 to 25 mg of hydrocortisone daily, which is roughly equal to 25 to 37.5 mg of cortisone acetate or 2.5 mg of prednisone.[54,65,67] The majority of the dose (67%) is given in the morning, whereas the remainder (33%) is given 6 to 8 hours later to duplicate the normal circadian rhythm of cortisol production. Since no laboratory test adequately determines the appropriateness of dosing, the patient's symptoms should be monitored every 6 to 8 weeks to assess proper glucocorticoid replacement.

In primary insufficiency, fludrocortisone acetate can be used to supplement mineralocorticoid loss. A dose of 0.05–0.2 mg by mouth once a day is adequate. If parenteral therapy is needed, 2 to 5 mg of deoxycorticosterone trimethylacetate in oil intramuscularly every 3 to 4 weeks can be substituted. Mineralocorticoid replacement attenuates the development of hyperkalemia, but may be unnecessary in all primary cases since glucocorticoids also contribute to mineralocortocoid binding. Adverse effects must be monitored closely. Symptoms include gastric upset, edema, hypertension, hypokalemia, insomnia, excitability, and diabetes mellitus. In addition, patient weight, blood pressure, and electrocardiogram should be monitored regularly.[65]

In women, the primary source of dehydroepiandrosterone (DHEA) and androgens is the adrenal cortex, specifically the zona reticularis. DHEA is converted to more potent androgens and estrogens in the periphery. Consequently, women with adrenal insufficiency can have decreased libido. DHEA, available as a dietary supplement, has been advocated as an option for female patients with adrenal insufficiency complaining of decreased libido and low energy.[68] However, clinical trial data for DHEA is conflicting, and a recent meta-analysis suggests no benefit for sexual well-being.[69] Given this limited efficacy and a lack of any standardization among the various commercial products, DHEA should not be used routinely in female patients to improve libido. DHEA may improve mood and well-being in select male and female patients who are already receiving optimal glucocorticoid and mineralocorticoid replacement.

Most adrenal crises occur secondary to glucocorticoid dose reduction or lack of stress-related dose adjustments. Patients receiving corticosteroid-replacement therapy should receive an additional 5 to 10 mg of hydrocortisone shortly before strenuous activities such as exercise.[65] Likewise, during times of severe physical stress such as febrile illnesses or injury, patients should be instructed to double their daily dose until recovery.[70,71] For major trauma, surgery, or in critically ill patients, larger doses are required. Parenteral therapy should be used for patients experiencing diarrhea or vomiting. In patients with concomitant, newly diagnosed, or uncontrolled hypothyroidism, thyroid replacement should take place only after adequate glucocorticoid replacement as euthyroidism can trigger an adrenal crisis by accelerating cortisol metabolism.[54]

The end point of therapy is difficult to assess in most patients, but a reduction in excess pigmentation is a good clinical marker. The development of features of Cushing's syndrome indicates excessive replacement. Treatment of secondary adrenal insufficiency is identical to primary disease treatment, except that mineralocorticoid replacement usually is unnecessary. Patient education is paramount with emphasis placed on the medication regimen and adrenal crisis prevention.

Acute Adrenal Insufficiency

Adrenal crisis, or Addisonian crisis, is characterized by an acute adrenocortical insufficiency. Adrenal crisis represents a true endocrine emergency. Anything that increases adrenal requirements dramatically can precipitate an adrenal crisis. Stressful situations, surgery, infection, and trauma all are potential triggering events, especially in the patient with some underlying adrenal or pituitary insufficiency. The most common cause of adrenal crisis is HPA-axis suppression brought on by chronic use of exogenous glucocorticoids and abrupt withdrawal.

Treatment of adrenal crisis involves the administration of parenteral glucocorticoids. Hydrocortisone is the agent of choice owing to its combined glucocorticoid and mineralocorticoid activity. Hydrocortisone is initially administered at a dose of 100 mg intravenously through rapid infusion, followed by a continuous infusion (usually 10 mg/hr) or intermittent bolus of 100 to 200 mg every 24 hours.[72] Intravenous administration is continued for 24 to 48 hours, at which time if the patient is stable, oral hydrocortisone can be administered at a dose of 50 mg every 6 to 8 hours, followed by tapering to the individual's chronic replacement needs. Fluid replacement often is required and can be accomplished with dextrose 5% in normal saline solution (D_5NS) at a rate to support blood pressure. During initial treatment for adrenal crisis, mineralocorticoid replacement generally is unnecessary because of hydrocortisone's mineralocorticoid activity (hydrocortisone 50 mg ≈ fludrocortisone 0.1 mg). If hyperkalemia is present after the hydrocortisone maintenance phase, additional mineralocorticoid supplementation can be achieved with 0.1 mg of fludrocortisone acetate daily.

Patients with adrenal insufficiency should be instructed to carry a card or wear a bracelet or necklace, such as MedicAlert, that contains information about their condition. Patients should also have easy access to injectable hydrocortisone or glucocorticoid suppositories in case of an emergency or during times of physical stress, such as febrile illness or injury.[65]

CLINICAL PRESENTATION: ADRENAL INSUFFICIENCY

Symptoms

- Patients commonly complain of weakness, weight loss, gastrointestinal symptoms, craving for salt, headaches, memory impairment, depression, and postural dizziness.
- Early symptoms of acute adrenal insufficiency also include myalgias, malaise, and anorexia. As the situation progresses, vomiting, fever, hypotension, and shock will develop.

Signs

- Increased pigmentation
- Hypotension (postural)
- Fever
- Decreased body hair
- Vitiligo
- Features of hypopituitarism (amenorrhea and cold intolerance)

Laboratory Tests

- The short corticotropin stimulation test can be used to assess patients suspected of hypercortisolism.

Other Diagnostic Tests

- Other tests include the insulin hypoglycemia test, the metyrapone test, and the corticotropin-releasing hormone stimulation test.

HYPOALDOSTERONISM

Hypoaldosteronism is rare and usually associated with low renin status (hyporeninemic hypoaldosteronism), diabetes, complete heart block, or severe postural hypotension, or it can occur postoperatively following tumor removal. Hypoaldosteronism can be part of a larger adrenal insufficiency or a standalone defect. In nonselective hypoaldosteronism, generalized adrenocortical insufficiency is the most likely etiology (see Addison's Disease). In selective hypoaldosteronism, insufficient aldosterone levels are precipitated by a specific defect in the stimulation of adrenal aldosterone secretion, with 21-hydroxylase deficiency being most common. Pseudohypoaldosteronism results from a defect in peripheral

aldosterone action, whether from increased peripheral resistance or a reduced number of functional aldosterone receptors.

Laboratory analysis reveals hyponatremia, hyperkalemia, or both. Patients often will present with hyperchloremic metabolic acidosis. In most cases, the deficiency is in mineralocorticoid production and replacement with fludrocortisone in a dose of 0.1 to 0.3 mg is usually effective. Patients should be followed for blood pressure response as well as electrolyte status.

CONGENITAL ADRENAL HYPERPLASIA

Because many enzyme systems are needed to complete the complex cholesterol-to-cortisol pathway, enzyme deficiencies can lead to disruptions of the normal cascade of events (see Fig. 85–2). This group of enzyme disorders is collectively referred to as congenital adrenal hyperplasia because of the resultant chronic adrenal gland stimulation that occurs following enzyme deficiency.[73,74] The most frequent cause of congenital adrenal hyperplasia is steroid 21-hydroxylase deficiency, accounting for more than 90% of cases. Any enzyme deficiency is capable of affecting any one or all three of the steroid pathways. Therefore, treatment focuses on replacement of the deficient hormone, psychologic support, and surgical repair of the external genitalia in most female patients.[75] Six of the most common enzyme deficiencies are outlined briefly in Table 85–8.

ADRENAL VIRILISM

9 Virilism, excessive secretion of androgens from the adrenal gland, commonly occurs as a result of congenital enzyme defects. Depending on the enzyme deficiency, patients accumulate excess levels of a variety of androgens, most notably testosterone. The condition affects females more often than males, with hirsutism being the dominant feature. Additional coexisting features can include voice deepening, acne, increased muscle mass, menstrual abnormalities, clitoral enlargement, redistribution of body fat and loss of female body contour, breast atrophy, and hair recession and crown balding.[76]

Treatment of virilism centers around suppression of the pituitary-adrenal axis with exogenous glucocorticoids. In adults, the usual steroids used are dexamethasone (0.25 to 0.5 mg), prednisone (2.5 to 5 mg), or hydrocortisone (10 to 20 mg).[77]

HIRSUTISM

Women presenting with hirsutism exhibit excess terminal hair growth in an androgen-dependent distribution. Such growth has obvious cosmetic consequences, but also can adversely affect quality-of-life and psychological well-being.[78] Most cases of hirsutism occur in women with some degree of excess androgen production. Androgen excess can be derived from either the ovaries or the adrenal glands, or rarely from pituitary disorders. Polycystic ovarian syndrome (PCOS) is responsible for most cases of ovarian excess and is the most common cause of hirsutism overall.[79] Congenital adrenal hyperplasia accounts for 5% of cases while adrenal and ovarian tumors cause hyperandrogenemia in 0.2% of women.

Cosmetic approaches generally are tried first, with repeated photoepilation offering the greatest long-term success.[79] If these approaches are unsuccessful, subsequent treatment should include pharmacologic intervention. Oral contraceptives are the treatment of choice in most hirsute women, particularly in those requiring concurrent contraception. If oral contraceptives are used, a progestin with low androgen activity (norethindrone, ethynodiol diacetate, or drospirenone) should be chosen. Antiandrogens, including spironolactone and finasteride, can supplement or replace oral contraceptive therapy in women who cannot or choose not to conceive. Antiandrogens can take 6 to 12 months to alleviate hirsutism and treatment should be continued for 2 years, followed by a slow dose reduction.[80] Glucocorticoids, such as dexamethasone, can be used if the androgen source is adrenal, but can induce cushingoid symptoms even in doses of 0.5 mg/day.

Gonadotropin-releasing hormone can be an effective adjunct or alternative to oral contraceptives if the source of androgen is ovarian. However, these products generally are not recommended due to excessive costs, injectible-only routes of administration, and adverse effects resulting from estrogen deficiency. Additionally, insulin sensitizers, such as metformin or thiazolidinediones, can show modest improvement in women with PCOS.

Eflornithine hydrochloride, an irreversible ornithine decarboxylase inhibitor, moderately reduces the rate of hair growth but does

TABLE 85-8 Congenital Adrenal Hyperplasia (CAH)

Enzyme Deficiency (Disorder)	Symptoms	Laboratory Tests	Comments
21-Hydroxylase (nonvirilizing CAH)	Enlarged female genitalia and adrenal gland (caused by cholesterol)	All steroids are low in blood and urine	Poor prognosis for infants
17-Hydroxylase (nonvirilizing CAH)	Hypertension usually present	Low concentrations of cortisol and estrogens	Mineralocorticoid replacement not necessary
21-Hydroxylase (virilizing CAH)	Pubertal irregularities (acne, early pubic hair, voice lowering, and increased muscularity); mature normally with replacement	High progesterone, renin, 17-hydroxyprogesterone and ACTH; low cortisol, sodium, and aldosterone	Most common form of CAH (90% of total), incidence of 1:10,000; monitor growth velocity, bone age, renin, and 17-hydroxyprogesterone
11-Hydroxylase (virilizing CAH)	Hypertension secondary to high deoxycortisol and virilism from androgen excess; mistaken for Cushing, but no glucose intolerance	Low plasma cortisone and aldosterone; high ACTH and MSH concentrations	Second most common form of CAH (9% of total), incidence of 1:100,000; final step in biosynthesis of corticosterone and cortisol; found only in adrenal cortex
3-Hydroxysteroid dehydrogenase (mixed CAH)	Both cortisol and aldosterone deficiencies	Decreased aldosterone, cortisol, estrogens, and androgens; increased pregnenolone and cholesterol	Defect affects both adrenals and gonads
18-Hydroxysteroid dehydrogenase (corticosterone methyloxidase deficiency)	Hypotension	Restricted to zona glomerulosa; sole aldosterone defect; hyponatremia, hyperkalemia, increased renin	Mineralocorticoid replacement without glucocorticoid replacement

ACTH, adrenocorticotropic hormone; MSH, melanocyte-stimulating hormone.

not remove hair already present. The drug is available as a topical cream that is applied as a thin layer to the affected area twice daily, at least 8 hours apart. Reduction in unwanted hair can be noted within 6 to 8 weeks with a maximal effect at 8 to 24 weeks.[77,81] Skin irritation can occur that resolves on discontinuation.

CLINICAL CONTROVERSY

Some clinicians believe that the usual starting doses for glucocorticoid supplementation are high and unnecessarily increase a patient's risk for adverse outcomes such as osteoporosis.

PRINCIPLES OF GLUCOCORTICOID ADMINISTRATION

Originally, the term *glucocorticoid* was given to these agents to describe their glucose-regulating properties. However, carbohydrate metabolism is only one of the myriad of effects exhibited by steroids. The activity produced by these drugs is a function of the receptor activated (glucocorticoid versus mineralocorticoid) as well as the agent and dose prescribed.

The mechanism of action of glucocorticoids is complex and not fully known. The glucocorticoid enters the cell through passive diffusion and binds to its specific receptor. Between 5,000 and 100,000 receptors exist in each cell. Steroids exhibit various binding affinities to the vast number of receptors in almost every tissue and therefore elicit a wide variety of biologic effects.

Following receptor binding, a structural change occurs in the receptor, known as *activation*. After activation, the receptor-steroid complex binds to deoxyribonucleic acid sites in the cell called *glucocorticoid response elements* (GREs). This binding stimulates or inhibits transcription of nearby genes.

Pharmacokinetic properties of the glucocorticoids vary by agent and route of administration. In general, most orally-administered steroids are well absorbed. Water-soluble agents are more rapidly absorbed following intramuscular injection than are lipid-soluble agents. Intravenous administration is recommended when a quick onset of action is needed. A summary of these agents is provided in Table 85–9.

In addition to causing iatrogenic Cushing's syndrome, systemic steroids can lead to increased susceptibility to infection, osteoporosis, sodium retention with resultant edema, hypokalemia, hypomagnesemia, cataracts, peptic ulcer disease, seizures, and generalized suppression of the HPA-axis. Long-term complications tend to be insidious and less likely to respond to steroid withdrawal.

Suppression of the HPA-axis is a major concern whenever systemic steroids are tapered or withdrawn. Single doses of glucocorticoids can prevent the axis from responding to major stressors for several hours. In general, steroid administration at a high dose for long periods of time causes suppression of the axis. However, the possibility of suppression occurs any time the patient is exposed to supraphysiologic doses of a steroid.[22,82] Symptoms of steroid withdrawal resemble those seen in a patient with adrenocortical deficiency.

A variety of recommendations for steroid tapering are available.[22,83–85] In general, patients who have been on long-term steroid therapy will need to be gradually withdrawn toward physiologic doses over months. On average, the normal adult produces approximately 10 to 30 mg of cortisol per day with the peak concentration occurring around 8:00 AM. As the steroid or steroid-equivalent dose approaches the 20- to 30-mg level, the taper should be slowed and the patient checked for axis function. The primary modes to test HPA integrity are the ACTH test, either high- or low-dose, or a morning (8:00 AM) serum cortisol. A normal morning serum cortisol (>20 mcg/dL) or a normal ACTH test indicates that daily steroid maintenance therapy may be discontinued. If morning serum cortisol is between 3 and 20 mcg/dL, the ACTH- or CRH-stimulation test can be useful in the assessment of pituitary-adrenal function.[22] A morning cortisol less than 3 mcg/dL indicates axis suppression and the need for continued replacement therapy. Suppression can persist for up to a year in some patients. Caution should be used to prevent disease exacerbation during the steroid taper and to avoid the need for rebolusing the patient with another course of high-dose steroids.

Alternate day therapy (ADT) regimens have been promoted by some as a means to lessen the impact of prolonged steroid administration.[22,85] ADT theoretically minimizes the hypothalamic-pituitary suppression as well as some of the adverse effects seen with once-daily therapy. This hypothetical advantage may be especially pertinent in treating children and young adults, in whom growth suppression is a major concern. ADT is not recommended for initial management, but rather in the management of the stabilized patient who needs long-term therapy. The patient is exposed to "on" and "off" days, with the "on" day dose gradually increased corresponding with a dose-reduction in the "off" day dose over a period of 14 days. After two weeks, no medication is taken on "off" days. Not all patients will have equivalent disease control on ADT, and it should be avoided in certain indications.[22,85]

TABLE 85-9 Relative Potencies of Glucocorticoids

Glucocorticoid	Anti-Inflammatory Potency	Equivalent Potency (mg)	Approximate Half-Life (min)	Sodium-Retaining Potency
Cortisone	0.8	25	30	2
Hydrocortisone	1	20	90	2
Prednisone	3.5	5	60	1
Prednisolone	4	5	200	1
Triamcinolone	5	4	300	0
Methylprednisolone	5	4	180	0
Betamethasone	25	0.6	100–300	0
Dexamethasone	30	0.75	100–300	0

CLINICAL CONTROVERSY

Some clinicians advocate thrice-daily dosing of glucocorticoids over twice-daily dosing as a means to more closely mimic physiologic variations in cortisol. Limited comparative data has favored three dose regimens, but most studies have serious methodologic flaws. If a thrice-daily regimen is used, the second dose should be administered at noon, followed by a third dose approximately 4 to 6 hours later.

EVALUATION OF THERAPEUTIC OUTCOMES

Successful glucocorticoid therapy involves counseling and monitoring the patient, as well as recognizing complications of therapy (Table 85–10). The risk-to-benefit ratio of glucocorticoid administration should always be considered, especially with concurrent disease states such as hypertension, diabetes mellitus, peptic ulcer disease, and uncontrolled systemic infections.

TABLE 85-10 Factors in Successful Glucocorticoid Therapy

Monitoring	Glucose concentrations (serum and urine) Electrolytes (serum and urine) Ophthalmologic examinations Stool tests for occult blood loss Growth and development (children and adolescents)
Counseling	Take with food to minimize gastrointestinal discomfort Never discontinue medication on your own; check with your physician; gradual dose reduction is usually necessary Carry or wear medical identification indicating that you are on long-term glucocorticoid therapy Dosage increases can be necessary at times of increased stress (surgery or emergency treatments) Be aware of potential side effects (i.e., visual disturbances, bruising, and delayed wound healing) What to do if you miss a dose: If your dosing schedule is *Every other day:* Take as soon as possible if remembered that morning. If not remembered until later, skip that day. Take the next morning, then skip the following day. *Every day:* Take as soon as possible, but skip if almost time for the next dose. Never double doses.
Recognizing complications	Early in therapy and essentially unavoidable: insomnia, enhanced appetite, weight gain Common in patients with underlying risk factors: hypertension, diabetes mellitus, peptic ulcer disease Long-term intense treatment: cushingoid habitus, hypothalamic-pituitary-adrenal suppression, impaired wound healing Delayed and insidious: cataracts, atherosclerosis Rare and unpredictable: psychosis, glaucoma, pancreatitis

From United States Pharmacopeial Convention[87] and Barlow.[88]

ABBREVIATIONS

ACTH: adrenocorticotropic hormone

ADT: alternate day therapy

APA: aldosterone-producing adenoma

APS: autoimmune polyendocrine syndrome

ARR: aldosterone-to-renin ratio

AVS: adrenal venous sampling

BAH: bilateral adrenal hyperplasia

CBG: corticosteroid-binding globulin

CHD: coronary heart disease

CrCL: creatinine clearance

CRH: corticotropin-releasing hormone

CT: computed tomography

D_5NS: dextrose 5% in normal saline solution

DDT: dichlorodiphenyltrichloroethane

DST: dexamethasone suppression test

FH: familial hyperaldosteronism

FST: fludrocortisone suppression test

GRA: glucocorticoid-remediable aldosteronism

GRE: glucocorticoid response element

HPA: hypothalamic-pituitary-adrenal

IPSS: inferior petrosal sinus sampling

IRMA: immunoradiometric assay

JNC: Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure

JVS: jugular venous sampling

MRI: magnetic resonance imaging

PAC:PRA: plasma-aldosterone-concentration–to–plasma-renin-activity (ratio)

PA: primary aldosteronism

RIA: radioimmunoassay

RU-486: mifepristone

UFC: urine free cortisol

CHAPTER 86

Pituitary Gland Disorders

AMY HECK SHEEHAN, JACK A. YANOVSKI, AND KARIM ANTON CALIS

KEY CONCEPTS

1. Pharmacologic therapy for acromegaly should be considered when surgery and irradiation are contraindicated, when there is poor likelihood of surgical success, when rapid control of symptoms is needed, or when other treatments have failed to normalize growth hormone (GH) and insulin-like growth factor 1 (IGF-1) concentrations.
2. Pharmacotherapy for acromegaly using dopamine agonists provides advantages of oral dosing and reduced cost compared to somatostatin analogs and pegvisomant. However, dopamine agonists effectively normalize IGF-1 concentrations in only 10% of patients. Therefore, somatostatin analogs remain the mainstay of therapy.
3. Blood glucose concentrations should be monitored frequently in the early stages of somatostatin analog therapy in all acromegalic patients.
4. Pegvisomant appears to be the most effective agent for normalizing IGF-1 concentrations. However, further study is needed to determine the long-term safety and efficacy of this agent for the treatment of acromegaly.
5. Recombinant GH is currently considered the mainstay of therapy for treatment of children with growth hormone-deficient (GHD) short stature. Prompt diagnosis of GHD and initiation of replacement therapy with recombinant GH is crucial for optimizing final adult heights.
6. All GH products are generally considered to be equally efficacious. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg/wk.
7. Pharmacologic agents that antagonize dopamine or increase the release of prolactin can induce hyperprolactinemia. Discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalize serum prolactin concentrations.
8. Cabergoline appears to be more effective than bromocriptine for the medical management of prolactinomas and offers the advantage of less frequent dosing and decreased adverse events.
9. Although preliminary data do not suggest cabergoline has significant teratogenic potential, cabergoline is not recommended for use during pregnancy, and patients receiving cabergoline who plan to become pregnant should discontinue the medication as soon as pregnancy is detected.
10. Pharmacologic treatment of panhypopituitarism consists of glucocorticoids, thyroid hormone preparations, sex steroids, and recombinant GH, where appropriate, as lifelong replacement therapy.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

In the 1950s, Geoffrey Harris and his colleagues uncovered the physiologic importance of pituitary hormones and proposed the theory of neurohormonal regulation of the pituitary by the hypothalamus.[1] Today the pituitary gland is recognized for its essential role in body homeostasis, and for this reason it is often referred to as the "master gland." The hypothalamus and the pituitary gland are closely connected, and together they provide a means of communication between the brain and many of the body's endocrine organs. The hypothalamus uses nervous input and metabolic signals from the body to control the secretion of pituitary hormones that regulate growth, thyroid function, adrenal activity, reproduction, lactation, and fluid balance.

ANATOMY AND PHYSIOLOGY

The hypothalamus (Fig. 86–1) is a small region at the base of the brain that receives autonomic nervous input from different areas of the body to regulate limbic functions, food and water intake, body temperature, cardiovascular function, respiratory function, and diurnal rhythms. In addition, the hypothalamus controls the release of hormones from the anterior and posterior regions of the pituitary gland. Neurons in the hypothalamus produce vasopressin and oxytocin and make many hormone-releasing factors that stimulate or inhibit the release of trophic hormones. At the base of the hypothalamus, a projection known as the *median eminence* is rich with nerve axons and blood vessels and provides both chemical and physical connections between the hypothalamus and the pituitary gland.

The pituitary gland, also referred to as the *hypophysis*, is located at the base of the brain in a cavity of the sphenoid bone known as the *sella turcica*. The pituitary is separated from the brain by an extension of the dura mater known as the *diaphragma sella*. The pituitary is a very small gland, weighing between 0.4 and 1 g in adults. It is divided into two distinct regions, the anterior lobe, or adenohypophysis, and the posterior lobe, or the neurohypophysis (see Fig. 86–1).

The posterior pituitary gland secretes two major hormones: oxytocin and vasopressin (antidiuretic hormone) (Table 86–1).

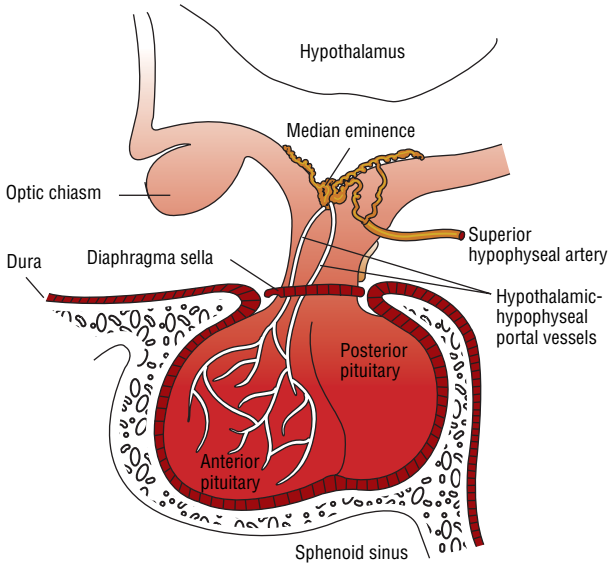

FIGURE 86-1. Pituitary gland.

Oxytocin release from the posterior pituitary causes contraction of the smooth muscles in the breast during lactation. It also plays a role in uterine contraction during parturition. Vasopressin is essential for proper fluid balance and acts on the renal collecting ducts to conserve water. Oxytocin and vasopressin are synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. The posterior pituitary gland contains the terminal nerve endings of these two nuclei as well as specialized secretory granules that release hormones in response to appropriate signals. Loss of anterior pituitary function does not necessarily affect the release of vasopressin or oxytocin because these hormones actually are synthesized in the hypothalamus.

Unlike the posterior pituitary, the release of anterior pituitary hormones is not regulated by direct nervous stimulation but rather is controlled by specific hypothalamic-releasing and inhibitory hormones. The median eminence of the hypothalamus contains a large number of capillaries that converge to form a network of veins known as the *hypothalamic–hypophysial portal circulation*. Inhibiting and releasing hormones synthesized in the neurons of the hypothalamus reach the anterior pituitary via the hypothalamic–hypophysial portal vessels to control release of anterior pituitary hormones. Although there is a direct arterial blood supply to the anterior pituitary lobe, the hypothalamic–hypophysial portal vessels provide the primary blood supply (see Fig. 86–1). In contrast to the posterior pituitary, the anterior pituitary lobe is extremely vascular and has the highest rate of blood flow of all body organs.

The specialized secretory cells of the anterior pituitary lobe secrete six major polypeptide hormones (see Table 86–1). These include growth hormone (GH) or somatotropin, adrenocorticotropic hormone (ACTH) or corticotropin, thyroid-stimulating hormone (TSH) or thyrotropin, prolactin, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The release of these hormones is regulated primarily by hypothalamic-releasing and inhibiting hormones. Thyrotropin-releasing hormone (TRH) stimulates anterior pituitary release of TSH and prolactin, corticotropin-releasing hormone (CRH) stimulates anterior pituitary release of ACTH, growth hormone-releasing hormone (GHRH) stimulates anterior pituitary release of GH, and gonadotropin-releasing hormone (GnRH) stimulates anterior pituitary release of LH and FSH. Hypothalamic release of somatostatin inhibits release of GH, and hypothalamic release of dopamine (prolactin inhibitory hormone) inhibits the secretion of prolactin. Prolactin differs from the other anterior lobe hormones in that an inhibiting factor, rather than a stimulating factor, is primarily responsible for controlling its secretion. In the absence of hypothalamic input, an excess of prolactin is produced, whereas a deficiency state of other anterior pituitary hormones results. Physiologic regulation and action of anterior and posterior pituitary hormones are summarized in Table 86–1.[2–4]

Destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, GH deficiency, and hypoprolactinemia. The formation of certain types of pituitary tumors may result in pituitary hormone excess. Pituitary tumors may physically compress the pituitary and prevent the release of trophic hypothalamic factors that regulate pituitary hormones. In this chapter, the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, short stature, hyperprolactinemia, and panhypopituitarism are discussed. (Also see Chapters 84, 85 and 87–91).

GROWTH HORMONE

GH has direct antiinsulin effects on lipid and carbohydrate metabolism. GH decreases utilization of glucose by peripheral tissues, increases lipolysis, and increases muscle mass. GH also stimulates gluconeogenesis in hepatocytes, impairs tissue glucose uptake, decreases insulin-receptor sensitivity, and impairs post-receptor insulin action. The growth-promoting effects of GH are largely mediated by insulin-like growth factors (IGFs) also known as *somatomedins*. GH stimulates the formation of insulin-like growth factor 1 (IGF-1) in the liver as well as in other peripheral tissues. This anabolic peptide acts as a direct stimulator of cell proliferation and growth. There are two types of insulin-like growth factors: IGF-1 and IGF-2. IGF-1 regulates growth to some extent before, and largely after, birth. In contrast, IGF-2 is thought to primarily regulate growth in utero.[5] GH is secreted by the anterior pituitary in a pulsatile fashion, with several short bursts that occur mostly at night. Because of the short half-life of GH in the plasma (~30 minutes), measurements of circulating GH concentrations throughout the waking hours usually are very low or undetectable. Daytime GH pulses are most likely to occur after meals, following exercise, or during periods of stress. The greatest amount of GH secretion occurs during the night within the first 1 to 2 hours of slow-wave sleep (stage III or IV). Secretion of GH is lowest during infancy, increases slightly during childhood, reaches its peak during adolescence, and then begins to gradually decline during the middle-age years.[3]

GROWTH HORMONE EXCESS

Acromegaly is a pathologic condition characterized by excessive production of GH. This is a rare disorder that affects approximately 50 to 70 adults per million.[6] Gigantism, which is even more rare than acromegaly, is the excess secretion of GH prior to epiphyseal closure in children.[7] Patients diagnosed with acromegaly are reported to have a 2- to 3-fold increase in mortality, usually related to cardiovascular, respiratory, or neoplastic disease.[8–10] Most patients are middle-aged at the time of diagnosis, and this disorder does not appear to affect one sex to a greater extent than the other. The most common cause of excess GH secretion in acromegaly is a GH-secreting pituitary adenoma, accounting for approximately 98% of all cases.[8] Rarely, acromegaly is caused by ectopic GH-secreting adenomas, GH cell hyperplasia, or excess GHRH secretion, or is one of the manifestations of multiple endocrine neoplasia syndrome type 1, McCune-Albright's syndrome, or the Carney complex, all very rare hypersecretory endocrinopathies.[8]

TABLE 86-1 Pituitary Hormones

Hormone	Stimulation	Inhibition	Physiologic Effects
Anterior pituitary hormones			
Growth hormone (GH)	*Physiologic*	*Physiologic*	
	GH-releasing hormone	Somatostatin	Stimulates IGF-I production
	Ghrelin	Elevated IGF-1	IGF-I and GH promote growth in all body tissues
	ADH	Growth hormone	
	GABA	Progesterone	
	Norepinephrine	Cortisol	
	Dopamine	Postprandial hyperglycemia	
	Serotonin	Elevated free fatty acids	
	Estrogen		
	Sleep		
	Stress		
	Exercise		
	Pharmacologic	*Pharmacologic*	
	α-Adrenergic agonists (e.g., clonidine)	Dopamine antagonists (e.g., phenothiazines)	
	β-Adrenergic antagonists (e.g., propranolol)	α-Adrenergic antagonists (e.g., phentolamine)	
	Dopamine agonists (e.g., bromocriptine)	β-Adrenergic agonists (e.g., isoproterenol)	
	GABA agonists (e.g., muscimol)	Serotonin antagonists (e.g., methysergide)	
Prolactin	*Physiologic*	*Physiologic*	
	TRH	Dopamine	Lactation
	VIP	GABA	
	Estrogen		
	Serotonin		
	Histamine		
	Endogenous opioids		
	Pregnancy and nursing		
	Pharmacologic	*Pharmacologic*	
	Dopamine antagonists (e.g., phenothiazines, haloperidol, methyldopa)	Dopamine agonists (e.g., L-dopa, bromocriptine, pergolide, cabergoline)	
	Opiates		
	Estrogens		
	H_2-antagonists (e.g., cimetidine)		
	MAO inhibitors		
Adrenocorticotropic hormone (ACTH)	CRH	Elevated cortisol	Glucocorticoid effects
			Pigmentation
Thyroid-stimulating hormone (TSH)	TRH	Thyroxine	Iodine uptake and thyroid hormone synthesis
	Estrogens	Triiodothyronine	
	Norepinephrine	Somatostatin	
	Serotonin	Glucocorticoids	
		Dopamine	
Luteinizing hormone (LH)	*Physiologic*		
	GnRH	Estradiol	Ovulation
	Pharmacologic	Testosterone	Maintains corpus luteum
	Clomiphene	Fasting	
Follicle-stimulating hormone (FSH)	*Physiologic*		
	GnRH	Estradiol	Ovarian follicle development
	Menopause	Inhibin	Stimulates estradiol and progesterone
	Ovarian disorders	Fasting	
	Pharmacologic		
	Clomiphene		
Posterior pituitary hormones			
Vasopressin (antidiuretic hormone [ADH])	Hyperosmolality	Hypervolemia	Acts on renal collecting ducts to prevent diuresis
	Volume depletion	Hypoosmolality	
Oxytocin	Parturition		Uterine contraction
	Suckling		Milk ejection

CRH, corticotropin-releasing hormone; GABA, γ-aminobutyric acid; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-like growth factor-1; MAO, monoamine oxidase; TRH, thyrotropin-releasing hormone; VIP, vasoactive intestinal peptide.

Data from Amar and Weiss,[2] Cuttler,[3] and Molitch.[4]

The clinical signs and symptoms of acromegaly develop gradually over an extended period of time. In fact, because of the subtle and slowly developing changes in physical appearance caused by GH excess, most patients are not definitively diagnosed with acromegaly until 7 to 10 years after the presumed onset of excessive GH secretion.[9] Excessive secretion of GH and IGF-1 adversely affects several organ systems. Almost all acromegalic patients will present with physical signs and symptoms of soft-tissue overgrowth. Table 86–2 summarizes the classic clinical presentation of patients with acromegaly.[8–13] Some patients with acromegaly present with only a few of these classic signs and symptoms, making recognition of this disease extremely difficult.

TABLE 86-2 Clinical Presentation of Acromegaly

General
The patient will experience slow development of soft-tissue overgrowth affecting many body systems. Signs and symptoms may gradually progress over 7 to 10 years.
Symptoms
The patient may complain of symptoms related to local effects of the growth hormone (GH)-secreting tumor, such as headache and visual disturbances. Other symptoms related to elevated GH and insulin-like growth factor-1 (IGF-1) concentrations include excessive sweating, neuropathies, joint pain, and paresthesias.
Signs
The patient may exhibit coarsening of facial features, increased hand volume, increased ring size, increased shoe size, an enlarged tongue, and various dermatologic conditions.
Laboratory tests
The patient's GH concentration will be >1 mcg/L following an oral glucose tolerance test (OGTT) and IGF-1 serum concentrations will be elevated. Glucose intolerance may be present in up to 50% of patients.
Additional clinical sequelae
• Cardiovascular diseases such as hypertension, coronary heart disease, cardiomyopathy, and left ventricular hypertrophy are common in patients with acromegaly.
• Osteoarthritis and joint damage develops in up to 90% of acromegalic patients.
• Respiratory disorders and sleep apnea occur in up to 60% of acromegalic patients.
• Type 2 diabetes develops in approximately 25% of acromegalic patients.
• Patients with acromegaly may have an increased risk for development of esophageal, colon, and stomach cancer.

Data from Ben-Shlomo and Melmed,[8] Melmed,[9] Kauppinen-Makelin et al.,[10] Fatti et al.,[11] Vitale et al.,[12] and Webb et al.[13]

The diagnosis of acromegaly is based on a combination of diagnostic tests and clinical signs and symptoms. Random measures of plasma GH levels are not usually dependable because of the pulsatile pattern of release. The oral glucose tolerance test (OGTT) is commonly used as an important diagnostic tool. Postprandial hyperglycemia inhibits the secretion of GH for at least 1 to 2 hours. Therefore, an oral glucose load would be expected to suppress GH concentrations. However, patients with acromegaly continue to secrete GH during the OGTT. Because GH stimulates the production of IGF-1, serum IGF-1 concentrations can also be measured to aid in the diagnosis of acromegaly. Circulating IGF-1 is cleared from the body at a much slower rate than is GH, and measurements can be collected at any time of the day to identify patients with GH excess.[9] Current criteria for the diagnosis of acromegaly include failure of GH suppression <1 mcg/L following an OGTT in the presence of elevated IGF-1 serum concentrations.[14,15] With the development of more sensitive GH and IGF-1 assays, the cutoff value for diagnosis of acromegaly will likely decrease in the future. Insulin-like growth factor 1 binding protein 3 (IGFBP-3) also can be measured because it is positively regulated by GH and binds to circulating IGF-1 with high affinity. This test may be useful in monitoring response to therapy.[8] Computed tomography and magnetic resonance imaging of the pituitary are important diagnostic tests to confirm the presence of a pituitary adenoma.[9,14,15]

TREATMENT

Acromegaly

The primary treatment goals for patients diagnosed with acromegaly are to reduce GH and IGF-1 concentrations, improve the clinical signs and symptoms of the disease, and decrease mortality.[15–17] Many clinicians define biochemical control of acromegaly as suppression of GH concentrations to <1 mcg/L after a standard OGTT in the presence of normal IGF-1 serum concentrations.[16] The treatment of choice for most patients with acromegaly is transsphenoidal surgical resection of the GH-secreting adenoma.[9,15,16] Postsurgical cure rates have been reported to range from 50% to 90%, depending on the type of adenoma and the expertise of the neurosurgeon.[8,16,17] Complications of transsphenoidal surgery are relatively infrequent and include cerebrospinal fluid leak, meningitis, arachnoiditis, diabetes insipidus, and pituitary failure.[8] For patients who are poor surgical candidates, those who have not responded to surgical interventions, or others who refuse surgical treatment, radiation therapy may be considered. Radiation, however, may take several years to relieve the symptoms of acromegaly.

Because neither radiation therapy nor surgery will cure all patients with acromegaly, adjuvant drug therapy is often needed to control symptoms.[9,17,18]

PHARMACOLOGIC THERAPY

1 Drug therapy should be considered for acromegalic patients in whom surgery and irradiation are contraindicated, when there is poor likelihood of surgical success, when rapid control of symptoms is indicated, or when other treatments have failed to normalize GH and IGF-1 concentrations. Pharmacologic treatment options include dopamine agonists, somatostatin analogs, and the GH receptor antagonist pegvisomant. Dopamine agonists such as bromocriptine and cabergoline are effective in a small subset of patients and provide the advantages of oral dosing and reduced cost. Somatostatin analogs are more effective than dopamine agonists, reducing GH concentrations and normalizing IGF-1 in approximately 50% to 60% of patients. Pegvisomant, a GH receptor antagonist, is highly effective in normalizing IGF-1 concentrations in up to 97% of patients. However, additional long-term data are needed to establish the safety and efficacy of pegvisomant in the management of acromegaly.

DOPAMINE AGONISTS

2 In normal healthy adults, dopamine agonists cause an increase in GH production. However, when these agents are given to patients with acromegaly, there is a paradoxical decrease in GH production. Most clinical experience with the use of dopamine agonists in acromegaly is with bromocriptine. Other agents such as pergolide, cabergoline, and lisuride also have been used. Bromocriptine is a semisynthetic ergot alkaloid that acts as a dopamine-receptor agonist. Most trials assessing the efficacy of bromocriptine in the treatment of acromegaly were conducted in the 1970s and early 1980s. These studies determined that certain subsets of acromegalic patients have a favorable response to drug therapy with bromocriptine. These patients include individuals with high circulating concentrations of prolactin and patients who experience GH suppression following a single 2.5-mg dose of bromocriptine, known as a *bromocriptine challenge*.[19] A review evaluating 34 studies concluded that therapy with bromocriptine was effective in suppressing mean serum GH levels to <5 mcg/L in approximately 20% of patients.[20] Only 10% of patients experience normalization of IGF-1 concentrations with bromocriptine therapy, but >50% of patients treated with bromocriptine experience improvement in acromegalic symptoms.[9,21]

In the United States, bromocriptine is commercially available as 2.5-mg oral tablets and 5-mg oral capsules. In acromegalic patients, significant reductions in GH concentrations are observed within 1 to 2 hours of oral dosing. This effect persists for at least 4 to 5 hours. An overall clinical response in acromegalic patients typically occurs

after 4 to 8 weeks of continuous bromocriptine therapy. For treatment of acromegaly, bromocriptine is initiated at a dose of 1.25 mg at bedtime and is increased by 1.25-mg increments every 3 to 4 days as needed.[19,20] Doses as high as 86 mg/day have been used for treatment of acromegaly, but clinical studies have shown that dosages >20 or 30 mg daily do not offer additional benefits in the suppression of GH.[20,21] When used for treatment of acromegaly, the duration of action of bromocriptine is shorter than that for treatment of hyperprolactinemia. Therefore, the total daily dose of bromocriptine should be divided into three or four doses.[19,21]

The most common adverse effects of bromocriptine therapy include central nervous system (CNS) symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, or diarrhea also are very common. Some patients may need to take bromocriptine with food to decrease the incidence of adverse gastrointestinal effects. Most adverse effects are seen early in the course of therapy and tend to decrease with continued treatment.[21] Bromocriptine may cause thickening of bronchial secretions and nasal congestion. Rare cases of psychiatric disturbances, pleural diseases, and an erythromelalgic syndrome (painful paroxysmal dilation of the blood vessels in the skin of the feet and lower extremities) have been reported with bromocriptine use. These conditions appear to be associated with higher doses and prolonged duration of therapy.[20,21]

Bromocriptine generally should be discontinued if a woman becomes pregnant while taking the drug. Surveillance of women who took bromocriptine throughout pregnancy does not suggest that bromocriptine is associated with an increased risk for birth defects.[21] If a woman becomes pregnant while taking bromocriptine, the risks and benefits of therapy should be fully considered. In most cases, the benefits of successful therapy outweigh the risks, and bromocriptine therapy should be continued if it is effective in improving symptoms and reducing elevated GH concentrations.

Other dopamine agonists that have been used to treat acromegaly include pergolide, cabergoline, lisuride, and quinagolide. Cabergoline may be especially useful in patients with pituitary tumors that secrete both prolactin and GH.[21,22] Quinagolide, a dopamine agonist available in Europe, has been shown to be more effective than both bromocriptine and cabergoline in normalizing GH and IGF-1 values in acromegalic patients.[19] Because of the potential cost advantages and convenience of oral administration, dopamine agonists are often considered for treatment of acromegaly prior to initiation of somatostatin analogs. However, the availability of long-acting somatostatin analogs has made these agents more attractive for first-line treatment of acromegaly.

SOMATOSTATIN ANALOGS

Octreotide and lanreotide are long-acting somatostatin analogs that are more potent in inhibiting GH secretion than endogenous somatostatin.[23,24] These agents also suppress the LH response to GnRH; decrease splanchnic blood flow; and inhibit secretion of insulin, vasoactive intestinal peptide (VIP), gastrin, secretin, motilin, serotonin, and pancreatic polypeptide.

Octreotide (Sandostatin) injection is commercially available in the United States for subcutaneous or intravenous administration. A long-acting intramuscular formulation of octreotide (Sandostatin LAR) is available for monthly administration. In addition to the treatment of acromegaly, octreotide has many other therapeutic uses, including the treatment of carcinoid tumors, vasoactive intestinal peptide-secreting tumors (VIPomas), gastrointestinal fistulas, variceal bleeding, diarrheal states, and irritable bowel syndrome.

The efficacy of octreotide for treatment of acromegaly has been determined by two major multicenter trials.[25,26] These studies determined that drug therapy with octreotide suppresses mean serum GH concentrations to <5 mcg/L and normalizes serum IGF-1 concentrations in 50% to 60% of acromegalic patients. Octreotide also is beneficial in reducing the clinical signs and symptoms of acromegaly. In a 6-month multicenter trial, 70% of patients experienced significant relief of headaches.[26] In some patients, relief of headache symptoms occurred within minutes of octreotide administration. In addition, middle-finger circumference was reduced significantly, and 50% to 75% of patients experienced improvement in symptoms of excessive perspiration, fatigue, joint pain, and cystic acne. Long-term follow-up of patients treated with octreotide LAR for up to 9 years showed octreotide therapy to be safe and effective for long-term use in acromegalic patients.[27] Octreotide also has been shown to improve the cardiovascular manifestations of acromegaly and to halt pituitary tumor growth, with some patients experiencing tumor regression.[25–28] Data from more recent studies indicate that shrinkage of pituitary tumor mass during octreotide therapy occurs in approximately 50% of patients.[29]

The pharmacodynamic effects of long-acting octreotide are similar to those of subcutaneously administered octreotide. Single monthly doses of long-acting octreotide have been shown to be at least as effective as daily doses of 300 or 600 mcg of subcutaneous octreotide administered in divided doses 3 times daily in normalizing IGF-1 levels and maintaining suppression of mean serum GH concentrations.[30] A large multicenter trial evaluating the efficacy of long-acting octreotide in acromegalic patients who previously had responded to subcutaneously administered octreotide reported suppression of GH concentrations to <5 mcg/L in 94% of patients and normalization of IGF-1 in 66% of patients following 1 year of therapy.[31]

Response to long-term therapy with octreotide is related to the presence and increased quantity of functioning somatostatin receptors located in the pituitary adenoma.[26] Identification of patients who most likely will respond to octreotide, prior to initiation of therapy, is important when considering the high cost of this medication and the inconvenience of subcutaneous or intramuscular drug administration. Suppression of serum GH concentrations after a single 50-mcg dose of octreotide has been used to predict a favorable long-term response to octreotide therapy.[32,33]

The initial dose of octreotide for treatment of acromegaly is 100 mcg administered every 8 hours.[18,20,24] Some clinicians recommend a starting dose of 50 mcg every 8 hours, then increasing the dose to 100 mcg every 8 hours after 1 week, to improve the patient's tolerance of adverse gastrointestinal effects. The dose can be increased by increments of 50 mcg every 1 to 2 weeks based on mean serum GH and IGF-1 concentrations. Patients who experience a significant rise in GH prior to the end of the 8-hour dosing interval may benefit from decreasing the dosing interval to every 4 to 6 hours. Although doses as high as 1,500 mcg/day have been used, doses >600 mcg daily generally do not offer additional benefits, and most patients are adequately managed with 100 to 200 mcg 3 times daily.[25,26] Patients who have been maintained on subcutaneous octreotide for at least 2 weeks and have shown response to therapy can be converted to the long-acting depot form of octreotide. The initial dose of long-acting octreotide is 20 mg administered intramuscularly in the gluteal region every 28 days. Steady-state serum concentrations are not obtained until after 3 months of therapy. Therefore, dosage adjustments for long-acting octreotide should not be considered until after this time. Some patients may require additional subcutaneous injections during the initial dose-titration phase in order to control symptoms. Long-acting octreotide doses >30 mg every 4 weeks have not been studied. A long-acting, intramuscular formulation of lanreotide (lanreotide LA) for twice monthly administration has been available in Europe for many years. Recently, a new formulation of lanreotide (Somatuline Depot) was approved for use

in the United States for monthly deep subcutaneous administration. The efficacy of this preparation of lanreotide for the treatment of acromegaly has been evaluated in several prospective multicenter clinical trials involving treatment-experienced patients who were switched from intramuscular octreotide LAR or intramuscular lanreotide LA to monthly deep subcutaneous lanreotide.[34–36] These studies have determined that deep subcutaneous lanreotide suppresses mean serum GH concentrations to <5 mcg/L and normalizes serum IGF-1 concentrations in acromegalic patients to a similar extent as octreotide LAR and lanreotide LA. A 4-year follow-up of 23 patients treated with monthly deep subcutaneous lanreotide reported the drug to be well tolerated during long-term therapy with mean serum GH concentrations <5 mcg/L in 62% of patients and normalization of serum IGF-1 concentrations in 43% of patients.[37] Well-designed trials directly comparing the efficacy of intramuscular octreotide LAR to deep subcutaneous lanreotide are currently lacking. However, these two agents are generally regarded to have comparable efficacy.[16]

Lanreotide (Somatuline Depot) is commercially available in the United States as 60-mg, 90-mg, and 120-mg prefilled syringes. In contrast to octreotide LAR, lanreotide injection does not need to be reconstituted prior to administration. The initial recommended dose of lanreotide is 90 mg given by deep subcutaneous injection in the superior external quadrant of the buttock every 28 days. Injection sites should be alternated between the left and right side. The initial dose should be reduced to 60 mg every 28 days for patients with moderate or severe renal or hepatic impairment. After 3 months of therapy, the dose may then be titrated based on serum GH concentrations, serum IGF-1 concentrations, and control of clinical signs and symptoms of acromegaly.[36] Long-acting deep subcutaneous lanreotide injection in doses >120 mg every 28 days has not been studied.

The most common adverse effects of somatostatin analog therapy are gastrointestinal disturbances such as diarrhea, nausea, abdominal cramps, malabsorption of fat, and flatulence.[16,23] Gastrointestinal adverse effects occur in approximately 75% of patients but usually subside within 10 to 14 days of continued treatment.[23] Octreotide has been reported to cause injection-site pain (4%–31%), conduction abnormalities and arrhythmias (9%), biochemical hypothyroidism (2%–12%), biliary tract disorders (4%–50%), and abnormalities in glucose metabolism (2%–18%).[20,23] Lanreotide has been reported to cause injection-site reactions (9%), sinus bradycardia (3%), hypertension (5%), biliary tract disorders (20%), and abnormalities in glucose metabolism (7%).[36]

Somatostatin analogs also inhibit cholecystokinin release and gallbladder motility, predisposing patients to the development of cholelithiasis.[23] The development of gallstones is a long-term adverse effect of somatostatin analog therapy and is largely dependent on geographic factors, dietary habits, and length of therapy.[20,24] The incidence of gallstones in acromegalic patients receiving octreotide and lanreotide increases with length of therapy and has been reported to range from 20% to 50%.[24–26] However, most patients are asymptomatic, and the diagnosis of cholelithiasis usually is made following an ultrasonographic study that is not prompted by patient symptoms. It has been estimated that only 1% of patients will develop symptomatic gallstones during 1 year of octreotide treatment.[24] Because somatostatin analog-induced gallstones usually are present without clinical symptoms, prophylactic cholecystectomy or medical therapy with ursodeoxycholic acid for acromegalic patients with asymptomatic gallstones usually is not recommended.[9,16] A small number of studies have suggested that the incidence of gallstone development may be lower with long-acting octreotide compared to subcutaneous octreotide.[30,31] However, further studies are needed to confirm this observation.

3 The effect of somatostatin analogs on glucose metabolism in patients with acromegaly is multifactorial. Decreases in serum GH concentrations induced by somatostatin analogs should result in decreased hepatic gluconeogenesis and increased insulin-receptor sensitivity. However, somatostatin analogs also decrease insulin secretion and increase IGFBP-1, which is known to inhibit the insulin-like effects of IGF-1. In addition, somatostatin analogs delay the gastrointestinal absorption of glucose, which may further alter glucose metabolism in acromegalic patients.[37] Small studies conducted in acromegalic patients receiving octreotide have reported improvement in insulin sensitivity as well as impaired insulin secretion.[38,39] Risk factors associated with worsening glucose tolerance included female sex and elevated baseline insulin values. Although somatostatin analogs appear to have a beneficial effect on glucose tolerance in most patients, glucose determinations should be obtained frequently in the early stages of therapy in all acromegalic patients.

GROWTH HORMONE RECEPTOR ANTAGONIST

4 Pegvisomant (Somavert) is a genetically engineered GH derivative that binds to, but does not activate, GH receptors and inhibits IGF-1 production by the liver. This agent is different from other medications used in the management of acromegaly because it does not inhibit GH production; rather, it blocks the physiologic effects of GH on target tissues. Therefore, GH concentrations remain elevated during therapy, and response to treatment is evidenced by a reduction in IGF-1 concentrations. Unlike somatostatin analogs, the pharmacologic activity of pegvisomant does not depend on the presence and quantity of somatostatin receptors in the pituitary tumor.[40] Studies evaluating the clinical efficacy of pegvisomant in acromegalic patients have reported a dose-dependent normalization of IGF-1 concentrations in 54% to 89% of patients after 12 weeks of therapy and in 97% of patients after 1 year of therapy.[40,41] Significant improvements in the clinical signs and symptoms of acromegaly were reported and persisted throughout the 1-year treatment period.[41] Adverse effects include injection-site pain, gastrointestinal complaints such as nausea and diarrhea, and flu-like symptoms. Significant elevations in hepatic aminotransferase concentrations, which are generally reversible upon discontinuation of the drug, have been reported in approximately 25% of patients.[16,42] As a result, hepatic function tests should be monitored very closely during therapy as outlined in the product labeling, and the drug should be used with caution in patients with baseline elevations in hepatic aminotransferase concentrations. GH concentrations increased significantly during the first 6 months of therapy. Tumor growth has been reported in a small number of patients and there are theoretical concerns that persistently elevated GH concentrations may stimulate tumor growth or result in other unfavorable long-term effects.

Pegvisomant is commercially available in the United States for daily subcutaneous use. The first dose should be administered under the supervision of a physician as a 40-mg loading dose. Subsequent doses are self-administered by the patient starting at a dose of 10 mg daily. The dose can be adjusted in 5-mg increments based on serum IGF-1 concentrations every 4 to 6 weeks, up to a maximum daily dose of 30 mg.[43]

Based on the available data, pegvisomant appears to be among the most effective agents for normalizing IGF-1 serum concentrations. However, it is very expensive and further study is needed to determine the long-term safety and efficacy of pegvisomant in the treatment of acromegaly. Current guidelines for acromegaly management suggest pegvisomant therapy for patients who have failed to achieve normalization of IGF-1 serum concentrations with other treatments.[16]

COMBINATION THERAPY

Several small studies have suggested that combination therapy with octreotide and dopamine agonists (bromocriptine or cabergoline) or octreotide and pegvisomant may be more beneficial than monotherapy with either drug alone.[20,23,44] Because of the potential for additive adverse effects, combination therapy should be considered as a therapeutic option only for refractory patients who have not fully responded to monotherapy.[16]

PHARMACOECONOMIC CONSIDERATIONS

Cost-effectiveness comparisons of the various treatment options for patients with acromegaly have not been performed. Considering that approximately 40% of patients are not completely cured after transsphenoidal surgery, pharmacologic treatment often becomes necessary. Bromocriptine and cabergoline are available as oral dosage forms and are considerably less expensive than octreotide, lanreotide, and pegvisomant. However, these agents are not effective in the majority of patients. Long-acting octreotide and lanreotide offer a convenient method of once-monthly administration for acromegalic patients, and may result in improved patient compliance, quality of life, and overall disease management. Pegvisomant appears to be the most effective agent for normalizing IGF-1 concentrations and may be useful in patients who are intolerant to or have not responded to therapy with dopamine agonists or somatostatin analogs. However, pegvisomant is significantly more expensive than long-acting octreotide or lanreotide and requires daily subcutaneous injections. Long-term studies evaluating the safety of pegvisomant are needed to clearly define its role in the management of acromegaly. The drug therapy of choice for an acromegalic patient should be determined by careful consideration of several patient-specific factors, including clinical response, compliance, tolerability, and cost of therapy.

CLINICAL CONTROVERSY

Some clinicians advocate the use of somatostatin analogs prior to surgery in order to improve comorbidities that may complicate surgery. However, sufficient evidence is lacking.

CONCLUSIONS

Acromegaly is a chronic debilitating disease characterized by excess GH secretion most commonly caused by a GH-secreting pituitary adenoma. Transsphenoidal surgical resection of the adenoma is the current treatment of choice for most patients with acromegaly. Patients who are poor surgical candidates may receive radiation therapy or long-term pharmacologic therapy. Drug therapy options within the United States for acromegaly include dopamine agonists, somatostatin analogs, and pegvisomant. Figure 86–2 shows a treatment algorithm for the management of acromegaly.[9,16]

GROWTH HORMONE DEFICIENCY

Short stature is a condition that is commonly defined by a physical height that is more than two standard deviations below the population mean and lower than the third percentile for height in a specific age group.[45–47] It has been estimated that more than 1.8 million children in the United States can be characterized as having short stature.[47] Short stature is a very broad term describing a condition that may be the result of many different causes. A true lack of GH is among the least common causes and is known as growth hormone-deficient (GHD) short stature. Absolute GH deficiency is a congenital disorder that can result from various genetic abnormalities, such as GHRH deficiency, GH gene deletion, and developmental disorders including pituitary aplasia or hypoplasia.[45,46] GH insufficiency is an acquired condition that can result secondary to hypothalamic or pituitary tumors, cranial irradiation, head trauma, pituitary infarction, and various types of CNS infections. In addition, psychosocial deprivation, hypothyroidism, poorly controlled diabetes mellitus, treatment of precocious puberty with LH-releasing hormone agonists, and pharmacologic agents such as glucocorticoids, methylphenidate, and dextroamphetamine may induce transient GH insufficiency.[45]

Short stature also occurs with several conditions that are not associated with a true GH deficiency or insufficiency. These conditions include intrauterine growth restriction; constitutional growth delay; malnutrition; malabsorption of nutrients associated with inflammatory bowel disease, celiac disease, and cystic fibrosis; chronic renal failure; skeletal and cartilage dysplasia; and genetic syndromes such as Turner syndrome.[45,46,48] In addition, many children are diagnosed with idiopathic or normal variant short stature. These patients have heights that are significantly lower than the third percentile but present with normal GH serum concentrations and no specific underlying explanation for short stature.[47]

Children with GHD short stature usually are born with an average birth weight. Decreases in growth velocity generally become evident between the ages of 6 months and 3 years.[45] In contrast, GH insufficiency may arise at any age during growth and development. The clinical characteristics of GHD or GH-insufficient children are listed in Table 86–3.[45,46]

Several factors must be considered in the diagnosis of GH deficiency or insufficiency. Standard epidemiologic growth charts developed by the National Center for Health Statistics typically are used to determine the percentile of anthropometric measurements, such as height, weight, and head circumference. Pubertal stage typically is determined using the Tanner method. Bone age is determined according to published standards, and growth velocity is calculated to determine the patient's height velocity percentile using standard growth-velocity charts.[45,46,48] GH deficiency is rarely seen in the absence of delayed skeletal maturation and decreased growth velocity. In addition, several different provocative stimuli that induce GH secretion may be used diagnostically to determine GH status. Common provocative pharmacologic GH stimuli include insulin-induced hypoglycemia, clonidine, L-dopa, arginine, glucagon, and GHRH.[46] A subnormal GH response during childhood is arbitrarily defined as a peak GH serum concentration <10 mcg/L during a 2-hour period after administration of one of these agents.[46] However, this maximum may be lower, depending on the specific assay and GH reference product used. For prepubertal and early pubertal patients (Tanner stage less than III), priming with sex hormones to improve the specificity of GH provocation tests is often considered. Some patients exhibit clinical signs of GH deficiency, subnormal growth velocity, and delayed bone age despite GH levels that are within normal limits after provocative testing. This makes diagnosis in this group of patients very difficult. Diagnosis based on GH stimulation tests becomes further complicated because of the paucity of data reporting the normal range of GH concentrations after provocative testing in healthy children and the fact that commercial GH and IGF-1 assays currently available may not be equivalent. Although a gold standard for diagnosis of GHD does not exist, treatment is generally recommended for children who have "idiopathic short stature" and pass GH provocative testing but have most of the following criteria: height greater than 2.25 standard deviations below the mean for age; subnormal growth velocity; delayed bone age; low serum IGF-1 and/or insulin-like growth factor binding protein 3 (IGFBP-3); and other clinical features consistent with GH deficiency.[49] Ultimately, careful consideration of multiple factors by a pediatric endocrinology specialist is required to correctly diagnose GH deficiency. Of note, more than half of children diagnosed with GH deficiency are found to secrete normal quantities of GH and IGF-1 in adulthood.[50]

TABLE 86-3 Clinical Presentation of Short Stature

General
• The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and sex.
Signs
• The patient will present with reduced growth velocity and delayed skeletal maturation.
• Children with growth hormone (GH)-deficient or GH-insufficient short stature may also present with central obesity, prominence of the forehead, and immaturity of the face.
Laboratory tests
• The patient will exhibit a peak GH concentration <10 mcg/L following a GH provocation test. Reduced insulin-like growth factor 1 and insulin-like growth factor 1 binding protein 3 concentrations may be present.
• Because GH deficiency may be accompanied by loss of other pituitary hormones, hypoglycemia and hypothyroidism may be noted.

Data from Hindmarsh and Brook[45] and American Association of Endocrinologists.[46]

TREATMENT

Growth Hormone Deficiency

PHARMACOLOGIC THERAPY

The treatment of GH deficiency with pituitary-derived human GH was first reported in the late 1950s. The National Hormone and Pituitary Program was founded by the National Institutes of Health in 1963 to coordinate the collection of human pituitary glands and purification of GH for administration to children with GH deficiency. In 1985, three deaths linked to Creutzfeldt-Jakob disease (CJD) were identified in young individuals who were previously treated with human pituitary GH. An evaluation of National Hormone and Pituitary Program data identified 26 cases of fatal CJD in a cohort of 6,107 patients who received treatment with human pituitary-derived GH in the United States between 1963 and 1985.[51] Human pituitary GH was withdrawn from the U.S. market because of the strong likelihood that the CJD was transmitted through contaminated human pituitary-derived GH. Shortly after the withdrawal of human pituitary GH, the U.S. Food and Drug Administration (FDA) approved the first recombinant DNA-derived GH for treatment of GH insufficiency. Prior to the introduction of recombinant GH, the number of individuals who received treatment for GH insufficiency was relatively small because of the limited availability of human pituitary tissue for GH extraction. Currently, with the widespread availability of recombinant GH products, a large number of children can receive GH replacement therapy at higher doses.

CLINICAL CONTROVERSY

Most pediatric endocrinologists in the United States believe that GH therapy is appropriate treatment in certain patients with non-GHD short stature. However, given the high cost of therapy and small increases in height, use of GH in this patient population remains controversial.

RECOMBINANT GROWTH HORMONE

5 Recombinant GH is currently considered the mainstay of therapy for treatment of GHD short stature. GH replacement therapy in children with documented GHD short stature produces a significant improvement in growth velocity within the first year of therapy and significantly improves final adult height.[52–55] The initial increase in growth velocity often is referred to as *catch-up growth*. Most of the initial studies evaluating the efficacy of GH therapy in GHD children were conducted for short periods of time in small numbers of patients, and, until recently, information about the long-term outcome of GH therapy was limited. Initial data suggested that final adult height is not substantially improved, with an average final adult height reported to be two standard deviations below the population mean.[56–59] Although these results were disappointing, it is important to note that a substantial percentage of patients included in these studies initially had received human pituitary GH in relatively low doses because of its limited availability. In addition, current GH dosing regimens with regard to frequency of administration have changed, making these data difficult to interpret and apply to patients who are receiving GH replacement therapy today. Recent studies evaluating the adult height of children who received only recombinant GH therapy with currently recommended dosing regimens suggest that current recombinant GH therapy has a greater impact on final adult height than previously reported.[52–55] These studies have reported average final adult heights ranging from 0.5 to 1.7 standard deviations below the population mean. Initiation of therapy at an early chronologic age, prior to the onset of puberty, is associated with a more favorable increase in final height.[46,53,54] Therefore, prompt diagnosis of GH deficiency and early initiation of replacement therapy with recombinant GH are crucial factors in optimizing the final adult height of children with GH deficiency.

Recombinant GH has been shown to increase the short-term growth rate in pediatric patients with chronic renal insufficiency, Turner syndrome, idiopathic short stature, Prader-Willi syndrome, short stature homeobox gene (SHOX) deficiency, Noonan syndrome, and children born small for gestational age (SGA), and is approved by the FDA for treatment of growth failure associated with these conditions. GH is also FDA approved for treatment of adult GH deficiency, short bowel syndrome in patients receiving specialized nutritional support, and acquired immunodeficiency syndrome wasting syndrome. When used in adult patients, the recommended dosage of recombinant GH is significantly lower than the dosage used in pediatric patients. Adult patients with GH deficiency during childhood must have the diagnosis of GH deficiency confirmed when they are adults. Long-term GH therapy in GHD adults significantly decreases body fat, increases muscle mass, and improves exercise capacity.[46] GH therapy in adults has been shown to improve the cardiac risk profile, bone mineral density, and psychological well-being.[60,61] In addition, GH currently is being investigated for a variety of disorders, including infertility, chronic fatigue, obesity, and natural aging.[46] Use of GH as an anabolic agent for management of acute catabolism is not recommended.[46]

The majority of short children in the United States do not have an identifiable medical cause for their condition, but with widespread availability of several recombinant GH formulations, many children have received GH therapy regardless of the underlying etiology of their short stature. The use of recombinant GH therapy in children with non-GHD short stature, also referred to as *idiopathic short stature*, has been studied by many investigators and was approved by the FDA in 2003.[62] However, the use of GH therapy in this patient population remains controversial. A meta-analysis of 38 clinical studies evaluating the efficacy of GH treatment in children with idiopathic short stature reported average increases in final adult height of 4 to 5 cm (1.6–2 inches) following a mean duration of therapy of 4.7 years.[63] This corresponded to an increase above the predicted final adult height of 0.56 to 0.63 standard deviations of the population mean. A more recently published randomized, double-blind, placebo-controlled trial with a mean GH treatment duration of 4.4 years reported an increase in final adult height of 3.7 cm (1.5 inches).[64] The slightly smaller height increase reported in the later study may be explained by the more stringent study design, lower mean GH doses, and GH treatment initiation at an older age (peripubertal) compared to the studies included in the meta-analysis.

6 Ten different recombinant GH products currently are available for use in the United States (Genotropin, Humatrope, Norditropin, Nutropin, Nutropin AQ, Omnitrope, Saizen, Serostim, Tev-Tropin, and Zorbtive) Each of these products contains somatropin. Somatropin is composed of the same amino acid sequence as human pituitary GH. Recombinant GH formulations must be administered by intramuscular or subcutaneous injection. Nutropin AQ, Norditropin, and omnitrope are the only GH products available as liquid formulations. The remaining products are formulated as lyophilized powders for injection, and patients must be instructed regarding proper administration. A needle-free injection device (Tject) is available for use with Tev-Tropin. This device delivers a thin stream of recombinant GH that penetrates the stratum corneum and deposits into the subcutaneous tissue. This product may be particularly useful for patients who experience significant adverse effects from injections. The potency of GH products is expressed as international units per milligram (international units/mg), with 1 mg containing approximately 2.6 international units of GH. Direct comparisons between the different recombinant GH products have not been published. However, all GH products are generally considered to be equally efficacious. The recommended dose for treatment of GHD short stature in children is 0.3 mg/kg/week.[46] Recombinant GH can be administered daily or in equal doses 6 times per week, depending on the specific GH product used.[46] Dosing regimens with greater frequency of administration have been shown to provide more favorable short-term growth responses.[46] GH replacement therapy should be initiated as early as possible after diagnosis of GH insufficiency and continued until a desirable height is reached or growth velocity has decreased to <2.5 cm per year after the pubertal growth spurt. However, the suitable time point for discontinuation of therapy with growth-promoting doses remains controversial. Glucocorticoids may inhibit the growth-promoting effects of recombinant GH, and concomitant administration of androgens, estrogens, thyroid hormones, or anabolic steroids may accelerate epiphyseal closure and compromise final height.

Three large databases, the National Cooperative Growth Study, the Kabi International Growth Study, and the Australian and New Zealand growth database (OZGROW), have been developed to collect postmarketing adverse effect data or reports associated with recombinant GH. Development of these databases was prompted by the unexpected and tragic cases of CJD reported

in patients treated with human pituitary GH. These databases are maintained by pharmaceutical companies that manufacture GH products.[65] Recombinant GH is generally well tolerated in children, and adverse effects are relatively uncommon.[65,66] A small number of patients may complain of injection-site pain or arthralgias. Idiopathic intracranial hypertension, also known as *pseudotumor cerebri*, has been reported in a very small number of children receiving GH therapy. This condition usually develops within the first 8 to 12 of weeks of treatment and presents with symptoms such as headache, blurred vision, diplopia, nausea, and vomiting.[65] The symptoms of idiopathic intracranial hypertension usually resolve after discontinuation of GH therapy, and long-term complications are rare. Cases of slipped capital femoral epiphysis have been reported in children with GH deficiency who are receiving GH therapy.[65] This condition is thought to occur as a result of the increased width of the femoral plate during GH treatment, but it also has been reported in GHD children who are not receiving GH replacement. Patients with this condition typically complain of hip or knee pain. Slipped capital femoral epiphysis can be managed by an orthopedic surgeon, and GH therapy does not need to be withdrawn. Because GH is known to cause decreased insulin sensitivity, hyperglycemia and diabetes mellitus may develop.[67] Patients who have specific predisposing risk factors for diabetes mellitus are at greatest risk for this adverse effect.[65–67] Glycosylated hemoglobin concentrations should be monitored in all patients receiving GH products.[46] GH may promote the growth of various types of neoplasms and increase tumor recurrence rates in patients with a history of malignancy.[46,65,66] For this reason, GH should not be administered to patients with an active malignant tumor or a history of recurrent tumor growth. In 1988, a Japanese report indicated that children receiving GH therapy were twice as likely to develop leukemia as children who were not receiving the hormone.[68] A more recent analysis of all collected reports of leukemia associated with GH therapy determined that these children had other leukemia risk factors (Fanconi's anemia, Bloom's syndrome, or history of cancer).[69] GH therapy in children without these risk factors does not appear to predispose children to develop leukemia.[65,66,69] Some patients may develop antibodies to recombinant GH. The development of antibodies during replacement therapy with recombinant GH products has been reported to be relatively low, affecting approximately 15% to 20% of patients.[70] More importantly, the presence of GH antibodies has not been shown to adversely affect growth response and appears to be clinically insignificant except in patients with GH gene deletions. Finally, recent postmarketing reports suggest an increased risk of death associated with long-term GH treatment in children with Prader-Willi syndrome who are severely obese or have severe respiratory impairment. GH treatment is contraindicated in patients with Prader-Willi syndrome who have any of these risk factors.

RECOMBINANT INSULIN-LIKE GROWTH FACTOR-1

Recombinant IGF-1 products, consisting of either IGF-1 alone (mecasermin [Increlex]) or IGF-1 in combination with IGFBP-3 (mecasermin rinfabate [Iplex]), have been recently approved by the FDA for the treatment of children with short stature due to severe primary IGF-1 deficiency (defined as children with height standard deviation score ≤−3.0 plus basal IGF-1 standard deviation score ≤−3.0, plus normal or elevated GH concentration) or GH gene deletion with neutralizing antibodies to GH. Recombinant IGF-1 products are not intended for use in subjects with secondary forms of IGF-1 deficiency, such as GH deficiency, malnutrition, hypothyroidism, or chronic treatment with pharmacologic doses of antiinflammatory steroids. Recombinant IGF-1 products have been shown to increase growth velocity in children with short stature who have low IGF-1 serum concentrations and resistance to GH.[71–74] However, the efficacy of these agents is less than that reported with GH products in patients with GH deficiency.

The recommended dose of mecasermin is 0.04 to 0.12 mg/kg administered by subcutaneous injection twice daily. Mecasermin rinfabate is administered by once-daily injections at a dose of 1 to 2 mg/kg. Because of the insulin-like effects of these products, patients should be monitored very closely for hypoglycemia, and the drug should be initiated at a dose at the lower end of the dosage range and administered with a meal or snack. The incidence of hypoglycemia may be less frequent with mecasermin rinfabate because of the longer half-life of the combination product.[71] Additional adverse effects experienced by patients receiving recombinant IGF-1 products include injection-site reactions, tonsillar/adenoidal hypertrophy, lymphoid hypertrophy, coarsening facial features, anaphylaxis, headache, dizziness, and arthralgia.[72,73,74] Intracranial hypertension has been reported in a small number of patients.[73] Additional studies are needed to elucidate the exact role of recombinant IGF-1 products in the management of short stature not caused by GH gene deletion or GH receptor defects.

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate monitoring of therapy for GHD and non-GHD short stature includes regular assessments of height, weight, growth velocity, serum alkaline phosphatase, and bone age every 6 to 12 months. Additional laboratory tests to monitor for potential adverse effects include serum glucose concentration and thyroid function. The dose of GH will periodically need to be increased as weight increases in growing children.

PHARMACOECONOMIC CONSIDERATIONS

The treatment of short stature with recombinant GH is expensive. Despite the prohibitive cost, recombinant GH remains the mainstay of therapy for children with GHD short stature. However, treatment of non-GHD short stature with recombinant GH is not widely accepted. The benefits in final adult height and increases in growth velocity, particularly in children with true GH deficiency, are associated with significant psychosocial benefits. Many clinicians believe that GH therapy can improve quality of life and should be made available to all children with short stature, regardless of whether or not they are GH deficient.[75] Until studies using recombinant GH more definitively demonstrate improvements in both final adult height and quality of life, the cost-effectiveness of GH, particularly for non-GHD short stature, remains uncertain.

CONCLUSIONS

GH deficiency during childhood results in short stature. Replacement with recombinant GH is considered the mainstay of therapy for patients with GHD short stature, but its use for treatment of non-GHD short stature remains controversial, albeit such treatment is FDA approved. Recombinant GH has proven to be safe for use in children and is associated with few adverse effects. The synthetic GHRH sermorelin and other GH-releasing peptides and preparations of IGF-1 may provide benefit for patients with non-GHD short stature. GH regimens can be particularly demanding and inconvenient for pediatric patients because they must be administered by subcutaneous injection. Knowledge of the long-term benefits and risks is critical to the development of rational, cost-effective treatments for patients with short stature.

PROLACTIN

PHYSIOLOGIC EFFECTS

Prolactin is secreted in a pulsatile fashion by the lactotroph cells of the anterior pituitary, with the highest peak concentrations observed during sleep.[4] The secretion of prolactin is regulated primarily by tonic hypothalamic inhibitory effects of dopamine. As described earlier in this chapter and as listed in Table 86–1, many factors can affect prolactin secretion. During pregnancy, prolactin serum concentrations rise substantially above normal. All other conditions characterized by excess prolactin serum concentrations, known as *hyperprolactinemia*, are considered pathologic.

HYPERPROLACTINEMIA

Hyperprolactinemia is a state of persistent serum prolactin elevation. Prolactin concentrations >20 mcg/L in women, and >25 mcg/L in men, observed on multiple occasions are generally considered indicative of hyperprolactinemia.[76,77] Hyperprolactinemia usually affects women of reproductive age.[76,78] The incidence of hyperprolactinemia in the general population is reported to be <1%.[77]

Hyperprolactinemia has several etiologies. The most common causes are benign prolactin-secreting pituitary tumors, known as *prolactinomas*, and various medications. Prolactinomas are classified according to size. Prolactin-secreting microadenomas are <10 mm in diameter and often do not increase in size.[4,77] In contrast, macroadenomas are tumors with a diameter >10 mm that continue to grow and can cause invasion of surrounding tissues.[4,77] In the presence of a prolactinoma, prolactin serum concentrations may remain normal or may be markedly elevated to thousands of micrograms per liter.

7 Any pharmacologic agent that antagonizes dopamine or increases the release of prolactin can induce hyperprolactinemia (Table 86–4). Serotonin is a strong stimulator of prolactin secretion, and selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, paroxetine, sertraline, and fluvoxamine are the medications most frequently associated with hyperprolactinemia.[79] Prior to the increased use of SSRIs, antipsychotic medications with potent dopamine-receptor blockade, such as the phenothiazine derivatives and haloperidol, were most often identified as the cause of drug-induced hyperprolactinemia.[86] Metoclopramide and domperidone, an antiemetic available in Europe, are potent dopamine-receptor antagonists reported to induce hyperprolactinemia.[79] Hormones such as estrogen and progesterone, commonly prescribed as oral contraceptives, can stimulate lactotroph growth to promote prolactin secretion and have been implicated in drug-induced hyperprolactinemia. Although the exact mechanism of action remains to be determined, the calcium channel-blocking agent verapamil has been associated with cases of hyperprolactinemia.[4,79] Methyldopa and reserpine, although not used frequently in clinical practice today, are antihypertensive agents that can stimulate prolactin secretion.[79] Prolactin concentrations may increase with administration of GnRH analogs such as leuprolide or goserelin.[79] Other medications rarely reported to cause hyperprolactinemia include H_2-receptor blocking agents, benzodiazepines, tricyclic antidepressants, dexfenfluramine, opioids, protease inhibitors, and monoamine oxidase inhibitors.[4,77,79] Prolactin levels do not typically rise to >150 mcg/L in cases of drug-induced hyperprolactinemia. Measurement of serum prolactin concentrations prior to the initiation of therapy with medications known to cause prolactin elevation may obviate the need for extensive examination of pituitary function and aid with the appropriate diagnosis of drug-induced hyperprolactinemia.

Verapamil

Data from Molitch,[4] Mah and Webster,[77] Gillam et al.,[78] and Molitch.[79]

Less common etiologies include CNS lesions that physically compress the pituitary stalk and interrupt tonic hypothalamic dopamine secretion, resulting in hyperprolactinemia.[77] Increased TRH concentrations in hypothyroidism can stimulate prolactin secretion and cause hyperprolactinemia. During conditions of renal or hepatic compromise, the clearance of prolactin is decreased, resulting in elevated prolactin concentrations.[4] Despite vigorous diagnostic effort, the cause of hyperprolactinemia cannot always be determined. This is known as *idiopathic hyperprolactinemia* and most likely is a result of the presence of very small tumors that are not detected by standard imaging techniques.[76] It should be noted that many physiologic factors, such as stress (including the stress of phlebotomy), sleep, exercise, coitus, and eating, also can induce transiently elevated prolactin levels.[4,76] This emphasizes the importance of obtaining multiple prolactin measurements to confirm the diagnosis. Ideally, after an intravenous line is placed in the patient's arm, the patient should rest in a supine position or in a chair for 2 hours before prolactin samples are collected.

Elevated prolactin serum concentrations inhibit gonadotropin secretion and sex-steroid synthesis.[76] Because prolactin concentrations >60 mcg/L are associated with anovulation, women with hyperprolactinemia typically present with menstrual irregularities such as oligomenorrhea or amenorrhea and infertility.[7,76,77] In addition, approximately 40% to 80% of women with hyperprolactinemia will have galactorrhea.[76,77] The clinical presentation of patients with hyperprolactinemia is summarized in Table 86–5.[4,76,77]

The diagnosis of hyperprolactinemia, as defined by multiple prolactin serum concentrations >20 mcg/L in women and >25 mcg/L in men, is relatively simple. However, identifying the underlying cause of this abnormality may be more challenging. Patients with modest prolactin elevations should have multiple prolactin serum determinations to minimize the potential for detecting only transient increases in prolactin. A careful medication history is essential, and the presence of hypothyroidism, renal failure, or hepatic dysfunction should be evaluated. If the cause of hyperprolactinemia remains ambiguous, a computed tomography scan or magnetic resonance imaging study should be performed to determine the presence of a pituitary tumor.[76,77] If an underlying cause of elevated prolactin serum concentration is not determined, the hyperprolactinemia is considered to be idiopathic.

TABLE 86-5 Clinical Presentation of Hyperprolactinemia

General

Hyperprolactinemia most commonly affects women and is very rare in men.

Signs and symptoms

- The patient may complain of symptoms related to local effects of the prolactin-secreting tumor, such as headache and visual disturbances, that result from tumor compression of the optic chiasm.
- Female patients experience oligomenorrhea, amenorrhea, galactorrhea, infertility, decreased libido, hirsutism, and acne.
- Male patients experience decreased libido, erectile dysfunction, infertility, reduced muscle mass, galactorrhea, and gynecomastia.

Laboratory tests

Prolactin serum concentrations at rest will be >20 mcg/L on multiple occasions.

Additional clinical sequelae

- Prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

Data from Molitch,[4] Schlechte,[76] and Mah and Webster.[77]

TREATMENT

Hyperprolactinemia

The treatment of hyperprolactinemia depends on the underlying cause of the abnormality. In cases of drug-induced hyperprolactinemia, discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalizes serum prolactin concentrations.[79] In cases for which an appropriate therapeutic alternative does not exist, medical therapy with dopamine agonists is warranted. Sex-steroid replacement also should be considered.[77] Treatment options for the management of prolactinomas include clinical observation, medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgical removal of the tumor.[4,76–78] Because prolactin-secreting microadenomas are very small and typically do not increase in size, treatment of these tumors is primarily directed toward alleviating symptoms.[76–78] The goal of therapy is to normalize prolactin serum concentrations and reestablish gonadotropin secretion to restore fertility and reduce the risk of osteoporosis. In patients with asymptomatic elevations in serum prolactin, observation and close follow up are appropriate.[76–78] For women with amenorrhea who do not wish to become pregnant, dopamine agonist therapy may not be necessary. In these patients, sex steroid replacement and close follow up may be sufficient.[76] Treatment goals are more aggressive in patients with prolactin-secreting macroadenomas because these tumors are larger and can cause invasion of local tissues with significant visual defects.[78] Therefore, in addition to normalizing prolactin concentrations, tumor shrinkage and correction of visual defects are primary goals of treatment.

Medical therapy with dopamine agonists usually is more effective than transsphenoidal surgery for both types of pituitary prolactinomas.[4,76–78] Postsurgical cure rates differ depending on tumor type and expertise of the neurosurgeon. Long-term cure rates are reported to be approximately 60% for microprolactinomas and only 25% for macroprolactinomas.[4] Transsphenoidal surgery for removal of prolactinomas usually is reserved for patients who are refractory to or cannot tolerate therapy with dopamine agonists and for patients with very large tumors that cause severe compression of adjacent tissues.[4,76–78] Radiation therapy may require several years for effective tumor shrinkage and reduction in serum prolactin concentrations and usually is used only in conjunction with surgery.[4]

PHARMACOLOGIC THERAPY

Medical therapy with dopamine agonists has proven to be very effective in normalizing prolactin serum concentrations, restoring menstruation, and reducing tumor size in approximately 80% to 90% of patients within 3 to 6 months of therapy.[4,77] Bromocriptine has been the mainstay of therapy since the 1970s. Cabergoline is a long-acting dopamine agonist that offers the advantage of less-frequent dosing. In recent years cabergoline has replaced bromocriptine as the agent of choice for the medical management of prolactinomas.

BROMOCRIPTINE

Bromocriptine was the first D_2-receptor agonist to be used in the treatment of hyperprolactinemia and has been the mainstay of therapy for over 20 years. It inhibits the release of prolactin by directly stimulating postsynaptic dopamine receptors in the hypothalamus. Hypothalamic release of dopamine (prolactin-inhibitory hormone) inhibits the release of prolactin. Decreases in serum prolactin concentrations occur within 2 hours of oral administration, with maximal suppression occurring after 8 hours and suppressive effects persisting for up to 24 hours. Medical therapy with bromocriptine normalizes prolactin serum concentrations, restores gonadotropin production, and shrinks tumor size in approximately 90% of patients with microprolactinomas and 70% of patients with macroprolactinomas.[78]

For the management of hyperprolactinemia, bromocriptine therapy typically is initiated at a dose of 1.25 to 2.5 mg once daily at bedtime to minimize adverse effects.[76,77] The dose can be gradually increased by 1.25-mg increments every week to obtain desirable serum prolactin concentrations. Usual therapeutic doses of bromocriptine range from 2.5 to 15 mg/day, although some patients may require doses as high as 40 mg/day.[77] Bromocriptine usually is administered in two or three divided doses, but once-daily dosing has also been shown to be effective.[78]

The most common adverse effects associated with bromocriptine therapy include CNS symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. Gastrointestinal effects such as nausea, abdominal pain, and diarrhea also are common. Bromocriptine should be administered with food to decrease the incidence of adverse gastrointestinal effects. Although most of these adverse effects diminish with continued treatment, approximately 12% of patients will not tolerate the adverse effects associated with bromocriptine therapy.[78] Vaginal preparations of bromocriptine have been studied in an effort to decrease the incidence of adverse effects associated with oral dosage forms.[4,77,81]

Because most patients with hyperprolactinemia are women with a principal complaint of infertility, the safety of bromocriptine in pregnancy must be considered. One report of 100 pregnancies in women who received bromocriptine throughout gestation did not detect an increase in the risk for spontaneous abortion or incidence of congenital anomalies.[78] Although bromocriptine does not appear to be teratogenic, most clinicians discontinue therapy as soon as pregnancy is detected because the effects of in utero exposure to bromocriptine on gonadal function and fertility of the offspring remain unknown.[4,76–78] In patients with macroprolactinomas undergoing rapid tumor expansion, bromocriptine therapy may need to be continued throughout pregnancy.

PERGOLIDE

Pergolide is a dopamine-receptor agonist with affinity for both D_1- and D_2-receptors. This agent is 10 to 1,000 times more potent than bromocriptine on a per milligram basis. In the United States, pergolide was never FDA approved for treatment

of hyperprolactinemia. However, it was used for many years as an effective alternative to bromocriptine in the management of patients with hyperprolactinemia and offered the advantage of once-daily dosing.[4,78] In 2007, pergolide was withdrawn from the U.S. market because of cases of cardiac valvulopathy.[82] Pathologic assessment suggested that the valvulopathy associated with pergolide appeared to be similar to that reported with other ergot alkaloids.

CABERGOLINE

8 Cabergoline is a long-acting dopamine agonist with high selectivity and affinity for dopamine D_2-receptors. This agent is approved for treatment of hyperprolactinemia and has been shown to effectively reduce serum prolactin concentrations in 80% to 90% of hyperprolactinemic patients.[83–85] Cabergoline also effectively reduces tumor size in patients with both microprolactinomas and macroprolactinomas.[83–86] In a multicenter randomized trial comparing the efficacy of cabergoline and bromocriptine, serum prolactin levels were normalized in 83% of patients receiving cabergoline and 58% of patients receiving bromocriptine after 6 months of therapy.[87] Cabergoline also has proved effective in patients who are intolerant of or resistant to bromocriptine, and data suggest that cabergoline is as effective in men as in women with microprolactinomas and macroprolactinomas.[85,88,89]

Cabergoline is commercially available as 0.5-mg oral tablets. The initial dose of cabergoline for treatment of hyperprolactinemia is 0.5 mg once weekly or in divided doses twice weekly. This dose may be increased by 0.5-mg increments at 4-week intervals based on serum prolactin concentrations.[90] The usual dose is 1 to 2 mg weekly; doses >3 mg per week are infrequently required.[91] However, doses as high as 12 mg weekly have been used safely in patients with treatment-resistant prolactinomas.[92] Following oral administration, peak serum concentrations are obtained within 2 hours, and food does not affect absorption. Data from animal studies indicate that cabergoline is widely distributed to well-perfused organs, including the pituitary gland.[90] The elimination of cabergoline from the pituitary appears to be very slow; this rate may explain the long duration of action. Cabergoline is extensively metabolized in the liver by hydrolysis, and the dose should be reduced in patients with severe hepatic failure. This drug is eliminated primarily in the feces, and the elimination half-life ranges from 79 to 155 hours in hyperprolactinemic patients.[90]

The most common adverse effects reported with use of cabergoline are nausea, vomiting, headache, and dizziness.[78,90] These effects are similar to the adverse effects reported with bromocriptine and pergolide. However, in a large comparative study evaluating bromocriptine and cabergoline, fewer patients receiving cabergoline reported adverse effects than did patients receiving bromocriptine, and only 3% of the patients in the cabergoline group withdrew from the study because of adverse effects versus 12% of patients taking bromocriptine.[87] Other adverse events associated with use of cabergoline include gastrointestinal complaints, drowsiness, fatigue, paresthesias, dyspnea, suffocation sensation, and epistaxis.[78,90] As with other dopamine agonists, adverse events usually occur early in therapy and subside with continued treatment. However, in one study 15% to 20% of patients receiving cabergoline experienced a recurrence of early symptoms or an onset of new symptoms after several weeks of treatment.[87] Mild-to-moderate decreases in blood pressure have been observed in up to 50% of patients taking cabergoline; however, the incidence of symptomatic orthostatic hypotension has not been significant.[83,84,87] Transient increases in serum alkaline phosphatase, bilirubin, and aminotransferases have been reported in small numbers of patients receiving cabergoline.[87] Pleuropulmonary disease[78] and newly diagnosed cardiac valve regurgitation[82] have been reported with cabergoline use at the larger doses used in the treatment of Parkinson's disease. Although symptomatic cardiac valve abnormalities have not been observed with cabergoline when administered in doses used for the treatment of prolactinomas, some clinicians have recommended routine echocardiography for patients receiving long-term cabergoline treatment for prolactinomas.[93,94]

9 Use of cabergoline in pregnancy has not been extensively studied. However, several case reports of women who received cabergoline therapy during the first and second trimesters of pregnancy have not documented an increased risk of spontaneous abortion, congenital abnormalities, or tubal pregnancy.[90,91] However, prospective data in large numbers of pregnancies are lacking. Because of the long half-life and limited data on cabergoline use in pregnancy, current guidelines recommend that women receiving cabergoline therapy who plan to become pregnant should discontinue the medication as soon as pregnancy is detected.[91]

Other dopamine agonists that have been used in the treatment of hyperprolactinemia but are not commercially available in the United States include lisuride, terguride, metergoline, dihydroergocristine, and quinagolide.[78] Quinagolide, a D_2-receptor agonist used frequently in Europe, is dosed once daily. Quinagolide has been shown to be as effective as bromocriptine for the management of hyperprolactinemia and may be effective in the treatment of patients who are resistant to or intolerant of bromocriptine.[78]

EVALUATION OF THERAPEUTIC OUTCOMES

Prolactin serum concentrations should be monitored every 3 to 4 weeks after the initiation of any dopamine-agonist therapy to assess efficacy and appropriately titrate medication dosage.[76] In addition, symptoms such as headache, visual disturbances, menstrual cycles in women, and sexual function in men should be evaluated to assess clinical response to therapy. Once prolactin concentrations have normalized and clinical symptoms of hyperprolactinemia have resolved with dopamine-agonist therapy, prolactin serum concentrations should be monitored every 6 to 12 months. In patients receiving long-term treatment, the dose of the dopamine agonist can be gradually reduced or discontinued in some patients. For patients with microprolactinomas who have normal serum prolactin concentrations and at least a 50% reduction in tumor size, medical therapy may be withdrawn every 2 to 5 years to assess if remission has been achieved. In the case of macroprolactinomas, the dose of the dopamine agonist can be gradually reduced in some cases, but complete drug discontinuation should be attempted only if careful monitoring for renewed tumor growth can be ensured.[76,91,95]

PHARMACOECONOMIC CONSIDERATIONS

Medical therapy with dopamine agonists is more effective than transsphenoidal surgery or radiation for the management of hyperprolactinemia. Because most patients receive therapy for long periods, the medical management of hyperprolactinemia may result in considerable cost. Cabergoline has been shown to be more effective than bromocriptine and offers additional advantages such as a decreased incidence of adverse effects and improved patient compliance. Most clinicians agree that cabergoline is the most efficacious dopamine agonist currently available. However, the cost of cabergoline therapy is approximately 2 times greater than that of bromocriptine. Pharmacoeconomic studies are needed to assess whether the higher cost of cabergoline therapy is balanced by the potential added benefits.

CONCLUSIONS

Hyperprolactinemia is a common disorder that can have a significant impact on fertility. Hyperprolactinemia is most commonly caused by the presence of prolactin-secreting pituitary tumors and various medications that antagonize dopamine or increase the secretion of prolactin. Available treatment options for this disorder include medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgery. In most cases, medical therapy with dopamine agonists is considered the most effective treatment. Cabergoline has replaced bromocriptine as the mainstay of medical therapy because it appears to be better tolerated and more effective. However, because of limited data regarding the safety of cabergoline during pregnancy, bromocriptine remains the preferred agent when fertility is the primary purpose for treatment.

PANHYPOPITUITARISM

⑩ Panhypopituitarism is a condition of complete or partial loss of anterior and posterior pituitary function resulting in a complex disorder characterized by multiple pituitary hormone deficiencies. Patients with panhypopituitarism may have ACTH deficiency, gonadotropin deficiency, GH deficiency, hypothyroidism, and hyperprolactinemia. Panhypopituitarism can be classified as either primary or secondary depending on the etiology. Primary panhypopituitarism involves an abnormality within the secretory cells of the pituitary, whereas secondary panhypopituitarism is caused by a lack of proper external stimulation needed for normal release of pituitary hormones. Some of the most common causes of panhypopituitarism include primary pituitary tumors, ischemic necrosis of the pituitary, surgical trauma, irradiation, and various types of CNS infections. Pharmacologic treatment of panhypopituitarism is essential and consists of replacement of specific pituitary hormones after careful assessment of individual deficiencies. Replacement most often consists of glucocorticoids, thyroid hormone preparations, and sex steroids. Administration of recombinant GH also may be necessary. Patients with panhypopituitarism will need lifelong replacement therapy and constant monitoring of multiple homeostatic functions.

SECTION 9
GYNECOLOGIC AND OBSTETRIC DISORDERS

CHAPTER 87

Pregnancy and Lactation: Therapeutic Considerations

KRISTINA E. WARD AND BARBARA M. O'BRIEN

KEY CONCEPTS

1. Physiologic changes modify drug pharmacokinetics during pregnancy, including changes in absorption, protein binding, distribution, and elimination, requiring individualized drug selection and dosing.
2. Although drug-induced teratogenicity is a serious concern during pregnancy, most drugs required by pregnant women can be used safely. Informed selection of drug therapy is essential.
3. Healthcare practitioners must know where to find and how to evaluate evidence related to the safety of drugs used during pregnancy and lactation.
4. Pregnancy-influenced health issues, such as constipation, gastroesophageal reflux disease, and nausea/vomiting, can be treated safely and effectively with nonpharmacologic treatment or carefully selected drug therapy. Some acute and chronic illnesses pose additional risks during pregnancy, requiring treatment with appropriately selected and monitored drug therapies to avoid harm to the woman and the fetus.
5. Understanding the physiology of lactation and pharmacokinetic factors affecting drug distribution, metabolism, and elimination can assist the clinician in selecting safe and effective medications during lactation.

Drug use in pregnancy and lactation is a topic often underemphasized in the education of health professionals. Drug use in pregnancy and lactation is a controversial and emotionally charged area because of medicolegal and ethical implications.

Clinicians are responsible for ensuring safe and effective therapy before conception, during pregnancy and parturition, and after delivery. Active patient participation is essential. Optimal treatments of illnesses during pregnancy sometimes differ from those used in the nonpregnant patient. Principles of drug use during lactation, although similar, are not the same as those applicable during pregnancy.

In many cases, medication dosing recommendations for acute or chronic illnesses in pregnant women are the same as for the general population. However, some cases require different dosing and selection of medications.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

PHYSIOLOGY OF PREGNANCY

Fertilization and progression of pregnancy are complex, resulting in survival of only approximately 50% of embryos.[1] Because most losses occur early, usually in the first 2 weeks after fertilization, many women don't realize they were pregnant. Spontaneous loss of pregnancy later in gestation occurs in about 15% of pregnancies that survive the first 2 weeks after fertilization.[2]

Fertilization occurs when a sperm attaches to a receptor on the outer protein layer of the egg, the zona pellucida, and renders the egg nonresponsive to other sperm.[3] The attached sperm releases enzymes that cause the egg's chromosomes to mature, allowing the sperm to fully penetrate the zona pellucida and contact the egg's cell membrane. The membranes of the sperm and egg then combine to create a new, single cell called a zygote. Male and female chromosomes join in the zygote, fuse to create a single nucleus, and organize for cell division.[4]

Fertilization usually occurs in the fallopian tube.[4] The fertilized egg travels down the fallopian tube over 2 days, with cell division taking place. By day 3, the fertilized egg reaches the uterus. Cell division continues for another 2 to 3 days in the uterine cavity before implantation. Approximately 6 days after fertilization, the cell mass is termed a *blastocyst*. Human chorionic gonadotropin (hCG) now is produced in amounts detectable by commercial laboratories. Implantation begins with the blastocyst sloughing the zona pellucida to rest directly on the endometrium allowing initiation of growth into the endometrial wall. By day 10 postfertilization, the blastocyst is implanted under the endometrial surface and receives nutrition from maternal blood.[4] Now it is called an *embryo*.[4,5]

After the embryonic period (between weeks 2 and 8 postfertilization), the conceptus is renamed a *fetus*.[5] Most body structures are formed during the embryonic period, and they continue to grow and mature during the fetal period. The fetal period continues until the pregnancy reaches term, approximately 40 weeks after the last menstrual period.[6]

Gravidity is the number of times that a woman is pregnant.[5,7] A multiple birth is counted as a single pregnancy. *Parity* refers to the number of pregnancies exceeding 20 weeks' gestation and relates information regarding the outcome of each pregnancy. In sequence, the numbers reflect (1) term deliveries, (2) premature deliveries, (3) aborted and/or ectopic pregnancies, and (4) number of living children. A woman who has been pregnant four times; has experienced two term deliveries, one premature delivery, and one ectopic pregnancy; and has three living children would be designated G_4P_{2113}.

PREGNANCY DATING

Pregnancy lasts approximately 280 days (about 40 weeks or 9 months); the time period is measured from the first day of the last menstrual period to birth.[5,7] *Gestational age* refers to the age of the embryo or fetus beginning with the first day of the last menstrual period, which is about 2 weeks prior to fertilization. When calculating the estimated due date, add 7 days to the first day of the last menstrual period then subtract 3 months. Pregnancy is divided into three periods of 3 calendar months, each called a *trimester*.

PREGNANCY SIGNS AND SYMPTOMS

Early symptoms of pregnancy include fatigue and increased frequency of urination. At approximately 6 weeks' gestation, nausea and vomiting can occur. While commonly called *morning sickness*, it can happen at any time of the day. Nausea and vomiting usually resolve at 12 to 18 weeks' gestation. A pregnant woman can feel fetal movement in the lower abdomen at 16 to 20 weeks of gestation. Signs of pregnancy include cessation of menses, change in cervical mucus consistency, bluish discoloration of the vaginal mucosa, increased skin pigmentation, and anatomic breast changes.[5,7]

MATERNAL PHARMACOKINETIC CHANGES IN PREGNANCY

1 Normal physiologic changes that occur during pregnancy may alter medication effects, resulting in the need to more closely monitor and, sometimes, adjust therapy. Physiologic changes begin in the first trimester and peak during the second trimester. For medications that can be monitored by blood or serum concentration measurements, monitoring should occur throughout pregnancy.

During pregnancy, maternal plasma volume, cardiac output, and glomerular filtration increase by 30% to 50% or higher, potentially lowering the concentration of renally cleared drugs.[8,9] As body fat increases during pregnancy, the volume of distribution of fat-soluble drugs may increase. Plasma albumin concentration decreases, which increases the volume of distribution of drugs that are highly protein bound. However, unbound drugs are more rapidly cleared by the liver and kidney during pregnancy, resulting in little change in concentration. Nausea and vomiting, as well as delayed gastric emptying, may alter the absorption of drugs. Likewise, a pregnancy-induced increase in gastric pH may affect the absorption of weak acids and bases. Higher levels of estrogen and progesterone alter liver enzyme activity and increase the elimination of some drugs but result in accumulation of others.

TRANSPLACENTAL DRUG TRANSFER

Although once thought to be a barrier to drug transfer, the placenta is the organ of exchange for a number of substances, including drugs, between the mother and fetus. Most drugs move from the maternal circulation to the fetal circulation by diffusion.[10] Certain chemical properties, such as lipid solubility, electrical charge, molecular weight, and degree of protein binding of medications, may influence the rate of transfer across the placenta.[10]

Drugs with molecular weights less than 500 Da readily cross the placenta, whereas larger molecules (600–1,000 Da) cross more slowly.[10] Drugs with molecular weights greater than 1,000 Da, such as insulin and heparin, do not cross the placenta in significant amounts.[10] Lipophilic drugs, such as opiates and antibiotics, cross the placenta more easily than do water-soluble drugs.[10] Maternal plasma albumin progressively decreases while fetal albumin increases during the course of pregnancy, which may result in higher concentrations of certain protein-bound drugs in the fetus.[10] Fetal pH is slightly more acidic than maternal pH, permitting weak bases to more easily cross the placenta. Once in the fetal circulation, the molecule becomes more ionized and less likely to diffuse back into the maternal circulation.[10]

DRUG SELECTION DURING PREGNANCY

2 Although some drugs have the potential to cause teratogenic effects, most medications required by pregnant women can be used safely. There are many misconceptions about the association of medications and birth defects.

The baseline risk for congenital malformations is approximately 3% to 6%, with approximately 3% considered severe.[2] Medication exposure is estimated to account for less than 1% of all birth defects.[2] Genetic causes are responsible for 15% to 25%, other environmental issues (e.g., maternal conditions and infections) account for 10%, and the remaining 65% to 75% of congenital malformations result from unknown causes.[2]

Factors such as the stage of pregnancy during exposure, route of administration, and dose, can affect outcomes.[2,11] In the first 2 weeks following conception, exposure to a teratogen may result in an "all-or-nothing" effect, which could either destroy the embryo or cause no problems.[11] During organogenesis (18 to 60 days postconception), organ systems are developing, and teratogenic exposures may result in structural anomalies. For the remainder of the pregnancy, exposure to teratogens may result in growth retardation, central nervous system abnormalities, or death.[2] Examples of medications associated with teratogenic effects in the period of organogenesis include chemotherapy drugs (e.g., methotrexate, cyclophosphamide), sex hormones (e.g., diethylstilbestrol), lithium, retinoids, thalidomide, certain antiepileptic drugs, and coumarin derivatives. Other medications such as nonsteroidal antiinflammatory drugs and tetracycline derivatives are more likely to exhibit effects in the second or third trimester.

In summary, a small number of medications have the potential to cause congenital malformations, and many can be avoided during pregnancy. In situations where a drug may be teratogenic but is necessary for maternal care, considerations related to route of administration and dosing may lessen the risk.

METHODS OF DETERMINING DRUG SAFETY IN PREGNANCY

3 When assessing the safety of using medications during pregnancy, an important consideration for the clinician is how to evaluate the quality of the evidence. Ideally, safety data from randomized, controlled trials is most desirable, but pregnant women are not usually eligible for participation in clinical trials. Other types of data commonly used to estimate the risk associated with medication use during pregnancy are animal studies, case reports, case-control

studies, prospective cohort studies, historical cohort studies, and voluntary reporting systems.

Animal studies are a required component of drug testing, but extrapolation of the results to humans is not always valid.[12] Thalidomide was found to be safe in some animal models but proved to have teratogenic effects in human offspring.

Case reports are usually of limited value because a birth defect in the infant of a woman who used a medication during pregnancy may have occurred by chance.[12] Case-control studies identify an outcome (congenital anomaly), match subjects with and without that outcome, and report how often exposure to a suspected agent occurred. Recall bias is a concern in case-control studies, as women with an affected pregnancy may be more likely to remember drugs used during the pregnancy than those who had a normal outcome.

Cohort studies evaluate the intervention (use of a particular drug) in a group of persons and compare outcomes in a similar group of subjects without the intervention.[12,13] Prospective studies eliminate some of the problems with recall bias but require time and large numbers of participants. Despite these disadvantages, cohort studies are often used for evaluating the effects of a drug exposure on pregnancy outcomes.

Teratology information services provide pregnant women with information about potential exposures during pregnancy and follow these women throughout the pregnancy to assess the outcomes of the pregnancy.[12] The services may publish pooled data to facilitate information sharing about medications used during pregnancy. Some pharmaceutical companies have organized voluntary reporting systems (also called pregnancy registries) for drugs used during pregnancy.

RESOURCES

3 Computerized databases (e.g., *www.motherisk.org*, LactMed [*www.toxnet.nlm.nih.gov*]), tertiary compendia, and textbooks with information from large cohorts of treated women offer valuable assistance. New information regarding drug use in pregnancy and lactation can be obtained from searches of the primary literature for cohort and case-control studies.

The Food and Drug Administration (FDA) developed risk categories (i.e., A, B, C, D, X, with A considered safe and X considered teratogenic) to guide clinicians regarding medication risk during pregnancy. The FDA ranks very few as safe during pregnancy (category A) because a controlled trial is required to establish safety; this implies that few drugs are safe. Because of multiple limitations of the risk categories, the FDA proposed a new system in 2008 to replace the risk categories with a fetal risk summary and lactation risk summary. Each section discusses clinical considerations and summarizes available data.[14]

In summary, drug safety information from product labeling may provide a rough estimate of risks for medication-related adverse fetal outcomes but must be used in conjunction with other information sources to make decisions about medication use in pregnant women.

GENERAL RECOMMENDATIONS FOR OPTIMIZING USE OF MEDICATIONS IN PREGNANCY

2 Medications are necessary during pregnancy for treatment of acute and chronic conditions. Identifying patterns of medication use before conception, eliminating nonessential medications and discouraging self-medication, minimizing exposure to medications known to be harmful, and adjusting medication doses are all strategies to optimize the health of the mother while minimizing the risk to the fetus.

PRECONCEPTION PLANNING

Pregnancy outcomes are influenced by maternal health status, lifestyle, and history prior to conception.[15] More than 60% of pregnancies in the United States are unintended. Of women who receive prenatal care, 18% seek it after the first trimester.[16] The goal of preconception care is health promotion, evidence-based screening, and intervention in all women of reproductive age to ensure optimal health and improve pregnancy outcomes.[15]

The most common major congenital abnormalities are neural tube defects (NTDs), cleft palate and lip, and cardiac anomalies. Each year in the United States approximately 1 in 1,000 infants are born with NTDs.[17] Folic acid supplementation substantially reduces the incidence in offspring of women, including those with a history of NTDs.[16,17] Neural tube defects occur within the first month of conception because neural tube closure occurs during the first month of pregnancy. Folic acid supplementation is recommended throughout a woman's reproductive years since many pregnancies are unplanned and may not be recognized until after the first month. Dietary intake of folic acid is not sufficient. For all women of childbearing age, folic acid supplementation with 400 mcg/day is recommended.[16] For women at high risk or those who have a history of NTDs, folic acid 4 mg/day is recommended. Multivitamins should not be used to achieve folic acid doses higher than contained in the multivitamin product because of risk for vitamin A toxicity.

Use of alcohol and recreational drugs during pregnancy is associated with birth defects.[15] Of births in the United States in 2003, 10% of mothers smoked tobacco during pregnancy.[15] Smoking can cause preterm birth, low birth weight, and other adverse outcomes. In a systematic review of 72 trials of smoking cessation and perinatal outcomes, incidences of low birth weight and preterm birth were reduced, and birth weight increased by 54 g with smoking cessation.[18] Cognitive behavioral therapy and nicotine replacement therapy resulted in similar rates of smoking cessation; however, offering incentives and social support resulted in the highest rate of success. For women who cannot stop smoking with behavioral interventions alone, nicotine replacement therapies can be used with behavioral therapy. Use of nicotine replacement during pregnancy is controversial since its use is not supported by clinical trial data; however, nicotine replacement theoretically imparts less risk than exposure to the over 4,000 chemicals found in cigarettes.[19] Intermittent delivery formulations are recommended because most users ingest a smaller total daily dose than received from the topically applied patch.[20] If patches are necessary because of poor tolerability of other agents, they should be applied for 16 rather than 24 hours per day. The initial dose of the patch should be similar or higher than that used for nonpregnant women because of nicotine's rapid metabolism during pregnancy. Bupropion is an alternative to nicotine replacement for women who have not quit smoking with behavioral therapy because the risk of its use appears to be less than that of cigarette smoking. However, its efficacy for smoking cessation in pregnancy has not been determined. Bupropion use during pregnancy should be reported to the GlaxoSmithKline pregnancy registry. Varenicline's safety and effectiveness during pregnancy are unknown.

Prevention of infectious disease during pregnancy is important. Vaccination against *Rubella* and hepatitis B as part of preconception care reduces adverse pregnancy outcomes.[15] Influenza vaccination is generally offered to women who will be in their second or third trimester during influenza season. Women with comorbid conditions that increase risks of complications from influenza should receive vaccine regardless of time of gestation.

PREGNANCY-INFLUENCED ISSUES

4 Pregnancy causes or exacerbates conditions that pregnant women commonly experience, including constipation, gastroesophageal reflux, hemorrhoids, and nausea and vomiting. Gestational diabetes, gestational hypertension, and venous thromboembolism have the potential to cause adverse pregnancy consequences. Gestational thyrotoxicosis is usually self-limiting.

GASTROINTESTINAL TRACT

The prevalence of constipation during pregnancy ranges from 25% to 40%. Light physical exercise and increased intake of dietary fiber and fluid should be instituted first.[21] If additional treatment is needed, supplemental fiber and/or a stool softener is appropriate.[22] Osmotic laxatives (polyethylene glycol, lactulose, sorbitol, and magnesium and sodium salts) are acceptable treatments but should be reserved for occasional use only. Polyethylene glycol is considered by some the ideal laxative for use in pregnancy.[21,22] Senna and bisacodyl can be used occasionally. Castor oil and mineral oil should be avoided.

Gastroesophageal reflux disease occurs in up to 80% of pregnant women.[21] An algorithm starting with lifestyle and dietary modifications (e.g., small, frequent meals; alcohol and tobacco avoidance; food avoidance before bedtime; elevation of the head of the bed) should be used. If symptoms are not relieved, use of antacids (aluminum, calcium, or magnesium preparations) or sucralfate is acceptable. Sodium bicarbonate and magnesium trisilicate should be avoided. Evidence supports the use of ranitidine and cimetidine. Literature evaluating the use of famotidine and nizatidine is limited, but they are likely safe. If a patient is unresponsive to lifestyle changes and histamine-2 receptor blockers, metoclopramide is a viable option. Relatively few data are available on the use of proton pump inhibitors during pregnancy; use should be reserved for women with complicated or intractable gastroesophageal reflux.

The prevalence of hemorrhoids during pregnancy is believed to be higher than in the general population.[23] Therapy during pregnancy is conservative (i.e., high intake of dietary fiber, adequate oral fluid intake, and use of sitz baths) and may be helpful; however, there is a paucity of supporting data for all management options. Topical anesthetics, skin protectants, and astringents can be used. Other options for refractory hemorrhoids include rubber band ligation, sclerotherapy, and surgery.

Nausea and vomiting affect up to 90% of pregnant women, usually beginning during the fifth week of gestation and lasting through the first trimester; however, about 15% of women experience it throughout pregnancy.[21,24] Hyperemesis gravidarum (HEG; i.e., unrelenting vomiting causing weight loss of more than 5% prepregnancy weight and ketonuria) occurs in about 1% to 3% of women.[24] Dietary modifications, such as eating frequent, small, bland meals and avoiding fatty foods, may be helpful. Applying pressure at acupressure point P6 on the volar aspect of the wrist may be beneficial.

A number of pharmacotherapeutic approaches have been tried for treatment of nausea and vomiting. Multivitamins, pyridoxine (vitamin B_6), and antihistamines (including doxylamine) have shown efficacy.[21,24] Phenothiazines and metoclopramide are widely used and generally considered safe.[21,24] Evidence of safety and efficacy with ondansetron is limited, but ondansetron can be considered for HEG when other treatments fail. Corticosteroids are effective for HEG but are associated with a small increase in the risk of oral clefts when used during the first trimester.[21,24] Ginger has shown efficacy for hyperemesis in randomized, controlled trials and is probably safe.[21,24]

GESTATIONAL DIABETES

Gestational diabetes mellitus (GDM) is glucose intolerance first identified during pregnancy. It develops in about 4% of pregnant women, although the prevalence may range from 1% to 14%.[25] Screening for gestational diabetes is controversial.[25–27] The U.S. Preventative Services Task Force Independent Expert Panel concluded that there is a lack of evidence proving that screening for gestational diabetes decreases adverse maternal and fetal outcomes.[27] However, the American Diabetes Association recommends glucose testing for women with risk factors of gestational diabetes (e.g., obesity, history of the condition, glycosuria, or strong family history of diabetes) at the first prenatal visit.[25] If normal, testing should be repeated between weeks 24 and 28 of gestation. Pregnant women considered to have average risk should undergo testing for GDM between weeks 24 and 28 of gestation unless they are considered low risk. To meet criteria for low risk, a woman must fulfill *all* the following: (a) age younger than 25 years, (b) normal body weight, (c) no known diabetes in first-degree relatives, (d) no history of abnormal glucose tolerance, (e) no history of adverse obstetric outcomes, and (f) not a member of an ethnic group with a high prevalence of GDM (e.g., African Americans, Native Americans, Asian Americans, Hispanic Americans, Pacific Islanders). Initial screening for hyperglycemia in pregnancy is similar to that in the general population and is described in the American Diabetes Association practice guidelines.[25]

Dietary modification is considered first-line therapy for all women who have GDM, with additional caloric restriction for obese women.[26,28] Daily self-monitoring of blood glucose is required. Insulin therapy with recombinant human insulin should be initiated if the following levels are not achieved with dietary modification: fasting plasma glucose concentrations below 90–99 mg/dL (5.0–5.5 mmol/L), 1-hour postprandial plasma glucose concentration less than or equal to 140 mg/dL (7.8 mmol/L), or 2-hour postprandial plasma glucose concentration below 120–127 mg/dL (6.7–7.0 mmol/L).[26] Glyburide is an alternative because it minimally crosses the placenta.[26,28] Metformin may also be an alternative, but it crosses the placenta and is less well studied than insulin or glyburide.[28] There are data, though limited, supporting the use of postprandial over preprandial blood glucose monitoring in women requiring insulin treatment.[29] Recommended targets for self-monitored blood glucose are preprandial plasma glucose concentration between 80 and 110 mg/dL (4.4–6.1 mmol/L) and 2-hour postprandial plasma glucose concentration below 155 mg/dL (8.6 mmol/L).[30]

Evidence supporting dietary modification, self-monitored blood glucose, exercise, and pharmacologic interventions for women with GDM is largely based on one randomized clinical trial that showed reductions in perinatal morbidity (composite of death, nerve palsy, bone fracture, and shoulder dystocia) with nutritional education, blood glucose monitoring, and insulin treatment.[31,32]

HYPERTENSION

Approximately 10% of pregnancies are complicated by hypertension at some time during the pregnancy. Hypertension in pregnancy is divided into four categories: chronic hypertension (preexisting hypertension), gestational hypertension (hypertension without proteinuria), preeclampsia (hypertension with proteinuria), and preeclampsia superimposed on chronic hypertension.[33,34] Treatment of mild-to-moderate hypertension (defined as systolic blood pressure 140–169 mm Hg or diastolic blood pressure 90–109 mm Hg) reduces the risk of severe hypertension by 50%, but does not substantially affect fetal outcomes. However, severe hypertension (blood pressure greater than or equal to 160–170 mm Hg

systolic or 110 mm Hg diastolic) can cause maternal complications, hospital admission, and potential premature delivery. Preeclampsia complicates 2%–8% of pregnancies and can cause poorer outcomes, including eclampsia (seizures in addition to preeclampsia), renal failure, coagulopathy, preterm delivery, and intrauterine growth restriction.[33]

Supplemental calcium 1–2 g/day decreases the relative risk of hypertension by 30% (range 14%–43%) and preeclampsia by 48% (range 31%–67%).[35] High-risk patients (those with the lowest initial calcium intake) benefited most; however, even women with adequate calcium intake at baseline had a 38% decrease in risk of preeclampsia. Therefore, 1 g/day of supplemental calcium is recommended for all pregnant women.

Nondrug managements center on activity restriction, psychosocial therapy, and biofeedback; however, no evidence indicates that any of these approaches improves pregnancy outcome, and prolonged bed rest may increase the risk of venous thromboembolic disease. Studies of antihypertensive drug therapy for mild-to-moderate hypertension (less than or equal to 160/110 mm Hg) in pregnancy have not conclusively shown a decrease in the risk of preeclampsia, neonatal death, preterm birth, or small-for-gestational-age babies. However, antihypertensives do prevent severe hypertension.[34,36] No evidence supports selection of one pharmacologic agent as first-line therapy. Commonly used drugs include methyldopa, labetalol, and calcium channel blockers.[36] Agents affecting the renin-angiotensin pathway (i.e., angiotensin-converting enzyme inhibitors, angiotensin receptor antagonists, and renin inhibitors) should probably be avoided throughout pregnancy.[36]

Drug therapy is indicated for women with blood pressure greater than or equal to 160/110 mm Hg. However, no consensus exists on when to initiate treatment, and recommendations vary from at least 140/90 mm Hg to 160/105 mm Hg.[36] As with mild-to-moderate hypertension in pregnancy, conclusive evidence supporting one antihypertensive agent over another is lacking, although agents to avoid include magnesium sulfate (unless indicated for eclampsia prevention), high-dose diazoxide, nimodipine, and chlorpromazine.[37]

Low-dose aspirin (75–81 mg/day) started after 12 weeks' gestation in women at risk for preeclampsia decreases the risk of its development by 17%, which corresponds to prevention of one preeclampsia case for every 72 at-risk women treated.[33,38] Low-dose aspirin also results in decreased rates of preterm birth (8% reduction) and fetal or neonatal death (14% reduction). In high-risk women (i.e., previous severe preeclampsia, renal disease, autoimmune disease, diabetes, and chronic hypertension), use of low-dose aspirin prevents one case for every 19 women treated. Features associated with moderate risk for preeclampsia include first pregnancy, adolescent maternal age, mild increase in blood pressure without proteinuria, abnormal uterine artery Doppler scan, family history of severe preeclampsia, and multiple fetuses; although some evidence refutes young maternal age as a risk factor.[33,38]

Preeclampsia may progress rapidly to eclampsia, a medical emergency, so signs and symptoms of preeclampsia must be monitored carefully. Eclampsia is the occurrence of seizures superimposed on preeclampsia.[33,39] Signs and symptoms of preeclampsia include blood pressure elevation; proteinuria; persistent severe headache; persistent new epigastric pain; visual changes; vomiting; hyperreflexia; sudden and severe swelling of hands, face, or feet; low platelet count; hemolytic anemia; increased serum creatinine; and elevated liver enzyme tests. The only cure for preeclampsia is delivery of the fetus. Treatment of hypertension in women with preeclampsia is the same as mentioned previously (e.g., methyldopa, labetalol, calcium channel blockers). Magnesium sulfate is recommended to prevent eclampsia as well as treat eclamptic seizures. Diazepam and phenytoin should be avoided.

THYROID ABNORMALITIES

During pregnancy, stimulation of the thyroid gland may occur because of hCG's structural similarity to serum TSH (thyrotropin).[40] In women with HEG, gestational transient thyrotoxicosis may result. Women are usually asymptomatic but may present with vomiting, increased serum free thyroxine, and decreased thyrotropin. Gestational transient thyrotoxicosis resolves as concentrations of hCG decline toward the end of the first trimester. Treatment with antithyroid medications is not usually needed. Nausea and vomiting can be treated as for patients without this pseudohyperthyroid state.

Postpartum thyroiditis occurs in approximately 4% of women within 1 to 4 months after childbirth because of increased thyroid hormone secretion.[41] Most cases resolve spontaneously; however, β-blockers (propranolol or labetalol) can provide symptomatic relief of adrenergic symptoms. Patients should be monitored since 2% to 5% of women go on to develop transient hypothyroidism 4 to 8 months postpartum; levothyroxine replacement is suggested for a total of 6 to 12 months. Up to 30% of women develop permanent hypothyroidism.

THROMBOEMBOLISM

Venous thromboembolism is estimated to occur in 0.06% to 0.13% of pregnancies; a five- to tenfold increase in risk over nonpregnant women.[42]

4 Unfractionated heparin or adjusted-dose low-molecular weight heparin are recommended for treatment of acute thromboembolism during pregnancy, although low-molecular-weight heparin is preferred.[42] Treatment should be continued throughout pregnancy and for 6 weeks after delivery. Warfarin is not used because it causes nasal hypoplasia, stippled epiphyses, limb hypoplasia, and eye abnormalities; the risk period appears to be between 6 and 12 weeks' gestation. However, central nervous system anomalies are associated with second- and third-trimester exposure. Antepartum monitoring or anticoagulation plus postpartum anticoagulation is recommended for women with a single episode of thromboembolism and either (a) thrombophilia, (b) an idiopathic cause without thrombophilia, or (c) a pregnancy- or estrogen-related risk factor. Antepartum and postpartum anticoagulation should be given to women with two or more episodes of thromboembolism, women with antithrombin III deficiency, and women receiving long-term anticoagulation. Pregnant women with antiphospholipid antibodies and a history of pregnancy complications should receive antepartum aspirin in addition to unfractionated heparin or low-molecular-weight heparin.

Women with prosthetic heart valves should receive low-molecular-weight heparin or unfractionated heparin during pregnancy.[42] After a discussion of potential risks, a heparin product can be used until week 13 of gestation with subsequent substitution of warfarin until the middle of the third trimester when a heparin product should again be used. High-risk women with prosthetic heart valves (e.g., older-generation mitral valve, history of thromboembolism) may also receive low-dose aspirin (75–100 mg/day).

CONCLUSION

Women with pregnancy-influenced gastrointestinal issues can be treated safely with lifestyle modification or medications, many of them nonprescription. Gestational diabetes, hypertension, and thyrotoxicosis may or may not require drug therapy. Venous thromboembolism treatment or prevention usually requires therapy with a low-molecular-weight heparin or unfractionated heparin.

ACUTE CARE ISSUES IN PREGNANCY

4 In some cases, the risks associated with the acute illness are magnified during pregnancy, and early screening and treatment become critical. In other cases, such as during treatment of certain sexually transmitted diseases, the urgency regarding treatment comes from an increased likelihood of infection leading to preterm labor. Occasionally, common acute care issues, such as migraine headache, improve during pregnancy.

URINARY TRACT INFECTION

4 The most common infections in pregnant and nonpregnant women are urinary tract infections.[43] The incidence of asymptomatic bacteriuria ranges from 2% to 10% while estimates for acute cystitis range from 1% to 4%. Untreated, bacteriuria progresses to pyelonephritis in 20% to 40% of pregnant women compared with 1% to 2% of nonpregnant women. Complications of pyelonephritis include premature delivery, low infant birth weight, hypertension, anemia, bacteremia, and transient renal failure.[44] A urine culture is recommended to screen pregnant women for urinary tract infections between 12 and 16 weeks' gestation.[43] Use of other methods, such as dipsticks that measure nitrites or leukocyte esterase, requires high bacterial concentrations for a positive result, leading to false negatives and underdiagnosis.

Escherichia coli is the primary cause of infection in 80% to 90% of cases.[43] Other gram-negative rods, such as *Proteus mirabilis* and *Klebsiella pneumoniae*, as well as Group B *Streptococcus* (GBS) account for some infections. The presence of GBS in the urine indicates heavy colonization of the genitourinary tract, increasing the risk for GBS infection in the newborn.

To decrease the risk of pyelonephritis and its complications, treatment of asymptomatic bacteriuria is necessary.[44] β-Lactams are not known teratogens; however, the incidence of *E. coli* resistance to ampicillin and amoxicillin limits their use as single agents. Cephalexin is safe and effective. Nitrofurantoin is also safe and effective, but it is not active against *Proteus* species. It should not be used after week 37 in patients with glucose-6-phosphate dehydrogenase deficiency because of a theoretical risk for hemolytic anemia in the neonate; however, no cases are reported. Sulfa-containing drugs can contribute to the development of newborn kernicterus; use should be avoided during the last weeks of gestation. Trimethoprim is a folate antagonist and is relatively contraindicated during the first trimester because of associations with cardiovascular malformations. Regionally, increased rates of *E. coli* resistance to trimethoprim-sulfa may limit its use. Fluoroquinolones and tetracyclines are contraindicated. The optimal duration of therapy for asymptomatic bacteriuria in pregnancy has not been determined. Courses of 7 to 14 days are common, but shorter courses of 3 days may be sufficient.[43] Repeat urine cultures are recommended monthly for the remainder of gestation if asymptomatic bacteriuria is diagnosed.

Signs and symptoms of acute cystitis include urgency, frequency, hematuria, pyuria, and dysuria.[43] Treatment of acute cystitis is similar to that of asymptomatic bacteriuria. Using outcomes of cure rates, recurrent infection, incidence of preterm delivery or rupture of membranes, admission to neonatal intensive care, need for change of antibiotic, or incidence of prolonged fever, antibiotic treatment has demonstrated effectiveness in treating symptomatic urinary tract infections (including pyelonephritis) in pregnancy.[45] No specific treatment appeared superior to other commonly used treatments.

Patients with pyelonephritis usually present with bacteriuria and systemic symptoms of fever, flank pain, nausea, and vomiting.[43] Hospitalization is the standard of care for pregnant women since many require intravenous hydration. Inpatient therapy has included parenteral administration of cephalosporins (e.g., cefazolin, ceftriaxone), ampicillin plus gentamicin, or ampicillin-sulbactam.[43,44] Switching to oral antibiotics can occur after the woman is afebrile for 48 hours. Outpatient antibiotic therapy can be considered after initial inpatient observation in women who are afebrile and less than 24 weeks' gestation. The total duration of antibiotic therapy for acute pyelonephritis is 10 to 14 days. Suppression therapy with nitrofurantoin 100 mg given nightly is recommended for the remainder of gestation because of the 20% recurrence rate.

SEXUALLY TRANSMITTED DISEASES

4 Sexually transmitted diseases in pregnant women range from infections that may be transmitted across the placenta and infect the infant prenatally (e.g., syphilis) to organisms that may be transmitted during birth and cause neonatal infection (e.g., *Chlamydia trachomatis, Neisseria gonorrhoeae*, or herpes simplex virus) to infections that pose a threat for preterm labor (e.g., bacterial vaginosis). Screening is essential for early detection of most sexually transmitted diseases but may not be beneficial in other instances (e.g., bacterial vaginosis in low-risk patients). Sexual partners of women with certain infections (e.g., syphilis, *N. gonorrhoeae, C. trachomatis*) also require treatment to prevent recurrence of infection.

Syphilis

Serologic testing for syphilis should occur during the first prenatal visit.[46] For women who live in areas with a high prevalence of syphilis, are at high risk, have not been previously tested, or had positive serology in the first trimester, additional serologic testing during the third trimester and at delivery is recommended. With the exception of neurosyphilis, which is treated with aqueous penicillin G, the drug of choice for all stages of syphilis is benzathine penicillin G. Penicillin effectively prevents transmission to the fetus and treats the fetus, if already infected. For pregnant women, the dose and route of administration are determined by the stage of syphilis and do not differ from recommendations for nonpregnant patients. No alternatives for penicillin are acceptable for penicillin-allergic pregnant women; therefore, penicillin skin testing and desensitization are required.

Treatment during the second half of pregnancy may increase the risk for preterm labor and fetal distress because a Jarisch-Herxheimer reaction may occur; however, treatment should not be withheld or delayed.[46] All women should have serologic titers repeated at 28 to 32 weeks' gestation, at delivery, and as dictated by recommendations for the stage of disease.

Neisseria gonorrhoeae

Perinatal gonococcal infection results from exposure to the infected cervix during birth. Symptoms usually manifest within 2 to 5 days after delivery.[46] Milder manifestations include rhinitis, vaginitis, urethritis, and infection at the site of fetal monitoring. More severe presentations include ophthalmia neonatorum and sepsis.

Coinfection with *C. trachomatis* is common; treatment of most *N. gonorrhoeae* infections includes treatment for *C. trachomatis*.[46] Cotreatment regimens for presumptive or diagnosed *C. trachomatis* infection are described in the following section. Ceftriaxone 125 mg intramuscularly as a single dose or cefixime 400 mg orally in a single dose is the treatment of choice for *N. gonorrhoeae* cervical infection. Women with a cephalosporin allergy or intolerance should receive a single dose of spectinomycin 2 g intramuscularly. Quinolones and tetracyclines are contraindicated.

TABLE 87-1 Recommended Regimens for Treatment of Cervical Infections Due to Chlamydia in Pregnancy

First-line treatment
Azithromycin 1 g orally in a single dose or
Amoxicillin 500 mg orally three times daily for 7 days
Alternative regimens
Erythromycin base 500 mg orally four times per day for 7 days or
Erythromycin base 250 mg orally four times per day for 14 days
Erythromycin ethylsuccinate 800 mg orally four times per day for 7 days or
Erythromycin ethylsuccinate 400 mg orally four times per day for 14 days

Data from Centers for Disease Control and Prevention, Workowski KA, Berman SM Sexually transmitted diseases treatment guidelines, 2006. MMWR Recomm Rep 2006;55(RR-11):1–94.[46]

Chlamydia trachomatis

C. trachomatis infects the newborn through exposure to the infected cervix during delivery.[46] Perinatal infection most commonly causes conjunctivitis that develops 5 to 12 days postpartum. A subacute, afebrile pneumonia with an onset at ages 1 to 3 months may occur.

The treatment of choice for *C. trachomatis* cervicitis is azithromycin 1 g orally as a single dose or amoxicillin 500 mg three times daily for 7 days.[46] Erythromycin base or ethylsuccinate regimens are alternatives, but gastrointestinal intolerance and the required frequency of administration may limit patient acceptance. Erythromycin estolate increases the risk for hepatotoxicity and should be avoided (Table 87–1).

Genital Herpes

4 Neonatal herpes often occurs in infants born to women lacking clinical evidence of genital herpes.[46] The risk of neonatal transmission is under 1% for women with a history of recurrent herpes at term, but is 30% to 50% for women who initially acquire genital herpes during the first half of their pregnancy. However, because recurrent herpes is more common than initial episodes during pregnancy, it remains the cause for most cases of neonatal transmission.

Prevention strategies include counseling uninfected women to avoid intercourse during the third trimester with partners having known or suspected genital herpes infection.[46,47] Women with no history of orolabial herpes should avoid receptive oral sex during the third trimester with partners who have orolabial herpes. Prevention of genital herpes transmission to pregnant women using antiviral agents has not been studied.

All women should be asked about symptoms of genital herpes at the time of delivery and should be examined for lesions.[46,47] Women who have no symptoms (including prodromal symptoms) or lesions proceed with vaginal childbirth; however, those with evidence of an outbreak undergo cesarean section to decrease the risk of neonatal transmission.

Maternal use of acyclovir during the first trimester has not demonstrated an increased risk for birth defects.[46] Valacyclovir is an alternative.[47] Safety data with famciclovir are limited. For initial or recurrent episodes, most women receive oral acyclovir therapy while intravenous acyclovir is reserved for severe infections. Women with an initial outbreak late in pregnancy may receive acyclovir, cesarean section, or a combination of the two. Acyclovir use during the last month of pregnancy may reduce the frequency of cesarean section because of fewer recurrences. In women seropositive for herpes simplex virus but who have not experienced an outbreak, no data suggest a treatment benefit.

Bacterial Vaginosis

Bacterial vaginosis results from the lack of normal vaginal flora (i.e., *Lactobacillus* species) and replacement with anaerobic bacteria, mycoplasmas, and *Gardnerella vaginalis*.[46] It is a risk factor for premature rupture of membranes, preterm labor, preterm birth, spontaneous abortion, and postpartum endometritis. Women with a history of preterm delivery should undergo screening for asymptomatic bacterial vaginosis at the first prenatal visit.

For symptomatic and asymptomatic women at high risk for preterm delivery, the recommended treatment regimen is metronidazole 500 mg orally twice daily for 7 days, metronidazole 250 mg orally three times daily for 7 days, or clindamycin 300 mg twice daily for 7 days. Conflicting data exist with regard to treating women at low risk for preterm labor. Vaginal preparations (e.g., metronidazole gel, clindamycin cream) have not demonstrated reductions in the risk of adverse pregnancy outcomes associated with bacterial vaginosis. Use of intravaginal clindamycin cream during the second half of pregnancy has caused low birth weight and neonatal infections.

HEADACHE

4 Primary headaches (e.g., tension, migraine) in pregnant women are the most common types of headache.[48] Secondary headaches can also occur as a result of trauma, infection, preeclampsia, stroke, or cerebral venous thrombosis.

The majority of pregnant women with a history of migraine headaches experience symptom improvement during pregnancy. Eighteen percent to 86% of women improve, and the greatest improvements occur during the second and third trimesters.[48,49] Improvement is more likely in women who have migraine without aura and less likely in women with a history of menstrual migraine. Women with menstrual migraine are more likely to have postpartum recurrence.

Relaxation, stress management, and biofeedback are all effective nonpharmacologic treatment methods.[48,49] Acetaminophen (with or without codeine), codeine, or other narcotic analgesics can be used to treat headaches that do not respond to nonpharmacologic treatment. Aspirin should be avoided in the third trimester because it can cause narrowing of the ductus arteriosus, maternal and fetal bleeding, and decreased uterine contractility. Nonsteroidal antiinflammatory drugs (NSAIDs) are considered safe but are also contraindicated in the third trimester because of the potential for closure of the ductus arteriosus. Caffeine may be added to any of the foregoing treatments to improve response, but overuse may cause withdrawal headaches. Use of sumatriptan is controversial because of limited information about pregnancy outcomes with its use, but some clinicians recommend it for women who have not responded to other agents.[49] Ergotamine and dihydroergotamine are contraindicated. Metoclopramide can be used for patients who have migraine-associated nausea. Chronic, preventive treatment is reserved for women who have three to four severe episodes per month that are not responsive to other treatments. β-Blockers, such as propranolol, are commonly used but may be associated with side effects, including intrauterine growth retardation. Alternatives include calcium channel blockers and antidepressants.[48,49]

Tension headaches are less studied.[48,49] Most women report no change in the frequency or intensity of tension headaches. Tension headaches may be difficult to distinguish from secondary headaches. Primary treatments for tension headache are nonpharmacologic interventions, including exercise, biofeedback, and massage. Simple analgesics such as acetaminophen, ibuprofen, or caffeine are used if nonpharmacologic treatments fail. Opioids are rarely used.[48]

CHRONIC ILLNESSES IN PREGNANCY

4 For the majority of women and their healthcare providers, pregnancy is a new consideration for a previously diagnosed health condition. Medications used to treat the chronic illness can often be used throughout the pregnancy and during breast-feeding.

ALLERGIC RHINITIS AND ASTHMA

4 Asthma and rhinitis are common chronic illnesses in pregnancy. During pregnancy, asthma control may change and worsen maternal oxygenation resulting in significant health consequences in the mother and fetus. Rhinitis itself is unlikely to cause harm to the mother or fetus but may be associated with diminished quality of life.

Asthma affects approximately 8% of pregnancies.[50] During pregnancy almost equal proportions of patients have symptoms that worsen, improve, or remain unchanged.[51] Health consequences of untreated or poorly treated asthma include preterm labor, preeclampsia, intrauterine growth restriction, premature birth, low birth weight, and stillbirth; therefore, the treatment goal is symptom control.[51,52] Asthma is controlled when there are no daytime symptoms, limitations of activities, nocturnal symptoms, short-acting β_2-agonist use, or exacerbations, and there is normal pulmonary function.

Caring for patients with asthma should include (a) assessment and monitoring (including measures of pulmonary function), (b) identifying and controlling exposure to allergens and irritants (e.g., tobacco smoke), (c) patient education, and (d) a stepped approach to medication use.[51] The risks of medication use to the fetus are lower than the risks of untreated asthma.

Treatment recommendations are divided into six steps based on symptom control.[51,52] A short-acting β_2-agonist is recommended for all patients with asthma for quick relief of symptoms. For mild intermittent asthma, Step 1 recommends only a short-acting, inhaled β_2-agonist; albuterol is preferred during pregnancy.

Initiation of treatment for persistent asthma should begin with Step 2 unless the patient has severely uncontrolled asthma, in which case treatment may start at Step 3.[51,52] For persistent asthma, step-appropriate doses (low, medium, high) of inhaled corticosteroids form the foundation of the controller medication regimen. When possible, low-dose inhaled corticosteroids are the treatment of choice for women with mild persistent asthma. Budesonide is preferred during pregnancy, although other inhaled corticosteroids that were effective before pregnancy can be continued. Long-acting β_2-agonists are considered safe to use during pregnancy because of the similar pharmacologic and safety profiles compared with short-acting agents; use should follow the stepwise approach.[50–52] Cromolyn, leukotriene receptor antagonists, and theophylline are considered alternative treatments but are not preferred because they are less effective (cromolyn), there is less experience with them (leukotriene receptor antagonists), and there is more potential toxicity (theophylline) than with inhaled corticosteroids. For patients with the most severe disease, addition of systemic corticosteroids is recommended to gain control of symptoms.[51]

Allergic rhinitis may also improve, worsen, or remain the same during pregnancy.[53] Treatment strategies include avoidance of allergens, immunotherapy, and pharmacotherapy. Immunotherapy is not contraindicated in pregnancy, but dose increases during pregnancy are not advised to lessen risk for anaphylaxis.

First-line medications to treat allergic rhinitis during pregnancy include intranasal corticosteroids, nasal cromolyn, and first-generation antihistamines (e.g., chlorpheniramine, hydroxyzine).[53] Intranasal corticosteroids are the most effective treatment and have a low risk of systemic effect; beclomethasone and budesonide have been most widely studied.[53,54] Second-generation antihistamines (i.e., loratadine and cetirizine) do not appear to increase fetal risk but are less extensively studied than first-generation products. Oral decongestants, such as pseudoephedrine, may be associated with an increased risk for the rare birth defect gastroschisis. Use of an external nasal dilator, short-term topical oxymetazoline, or inhaled corticosteroids may be preferable to use of oral decongestants, especially during early pregnancy.

DERMATOLOGIC CONDITIONS

4 Treatment of dermatologic conditions can often be delayed until after the delivery.[55] If treatment is required during gestation, topical agents considered to have minimal pregnancy risk include bacitracin, benzoyl peroxide, ciclopirox, clindamycin, erythromycin, metronidazole, mupirocin, permethrin, and terbinafine. Topical corticosteroids are generally considered safe for use but should be applied at the lowest possible dose for the shortest time. Systemic agents considered safe include acyclovir, amoxicillin, azithromycin, cephalosporins, cyproheptadine, dicloxacillin, diphenhydramine, erythromycin (except estolate), nystatin, and penicillins. Lidocaine and lidocaine with epinephrine can be used topically during pregnancy. Acitretin, fluorouracil, isotretinoin, methotrexate, and thalidomide should be avoided because of teratogenic potential.

DIABETES

4 Poorly controlled diabetes can cause fetal malformations and fetal loss.[30] Women with diabetes should use effective contraception until optimal glycemic control is achieved before attempting pregnancy. Additionally, diabetic retinopathy may worsen, hypertension may develop, and renal function may deteriorate during pregnancy, requiring enhanced monitoring for these target-organ problems.[56]

For patients with both type 1 and type 2 diabetes, insulin is the drug treatment of choice.[56] However, glyburide and metformin may be alternatives.[26,28] Medical nutrition therapy and supervised physical activity programs should continue. Goals for self-monitored blood glucose are the same as for gestational diabetes.[30,56]

EPILEPSY

4 Seizure frequency does not change for most pregnant women with epilepsy. Studies have demonstrated no frequency change in 54% to 80% of women with epilepsy, while decreased frequency ranges between 3% and 24% and increased frequency ranges from 14% to 32%.[57,58] Seizures may become more frequent because of changes in maternal hormones, sleep deprivation, and medication adherence problems (because of perceived teratogenic risk). Another potential cause is changes in free serum concentrations of antiepileptic drugs resulting from increased maternal volume of distribution, decreased protein binding from hypoalbuminemia, increased hepatic drug metabolism, and increased renal drug clearance. A woman's clinical condition and her free serum concentrations of antiepileptic drug should be the basis for dose adjustments.

The risks of untreated epilepsy to the fetus are considered to be greater than those associated with the antiepileptic drugs.[58] Major malformations are two to three times more likely to occur in children born to women taking antiepileptic drugs than to those who do not. Major malformations with valproic acid are dose related and range from 6.2% to 10.7%; use of valproic acid should be avoided if possible during pregnancy to minimize the risk of NTDs (e.g., spina bifida), facial clefts, and cognitive teratogenicity.[59,60] Rates of major malformation for monotherapy with antiepileptic drugs other than valproic acid range between 2.9% and 3.6%. Carbamazepine and lamotrigine appear to be safest based on available data. However, individual antiepileptic drugs are associated with malformations. Phenytoin, lamotrigine, and carbamazepine may cause cleft palate, while phenobarbital is associated with cardiac malformations. Polytherapy with antiepileptic drugs is associated with a greater rate of major malformation than monotherapy.[59,60]

When possible, antiepileptic drug monotherapy is recommended with medication regimen optimization occurring before

conception.[59] Medication change solely to minimize teratogenic risk is not recommended. If drug withdrawal is planned, it should be attempted at least 6 months before attempting to conceive.[59] While vitamin K administration during the last month of gestation was previously recommended to decrease the risk of hemorrhagic complications in newborns, evidence to support this practice is lacking. The American Academy of Pediatrics recommends that all neonates receive vitamin K at delivery. All women taking antiepileptic drugs should receive folic acid supplementation; 4 to 5 mg daily starting before pregnancy and continuing through at least the first trimester.[58]

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

4 Pregnant women newly diagnosed with HIV, with or without prior treatment, should receive highly active antiretroviral therapy (HAART). The treatment regimen should be selected from those suggested for nonpregnant adults, with special consideration given to the teratogenic profile of each drug.[61] Women currently receiving antiretroviral treatment should be continued on their regimen when possible. If antiretroviral drugs are being used exclusively to prevent mother-to-child transmission, prophylaxis may be delayed until after the first trimester.

Zidovudine is the mainstay of antiretroviral therapy and is recommended for use during pregnancy, labor, and delivery, as well as during the postpartum period.[61] Lamivudine should be used along with zidovudine as the nucleoside reverse transcriptase inhibitor (NRTI) backbone of therapy when feasible. For HAART, two NRTIs plus either a nonnucleoside reverse transcriptase inhibitor (NNRTI) or a protease inhibitor is recommended; current guidelines recommend nevirapine or lopinavir/ritonavir. Efavirenz should be avoided during the first trimester and the entire pregnancy if possible. If therapy is discontinued during the first trimester, reintroduction of all medications should occur only when the ability to tolerate drug therapy is certain. All medications should be restarted at the same time to decrease risk of resistance. Zidovudine dosing recommendations during pregnancy are 300 mg twice daily or 200 mg three times a day. Intravenous zidovudine is recommended during labor, and the infant should receive the drug beginning 6 to 12 hours after birth and continuing for the first 6 weeks of life.

HYPERTENSION

4 Treatment of stage 1 or 2 chronic hypertension (blood pressure 140–179 mm Hg systolic or 90–109 mmHg diastolic) during pregnancy is controversial because the physiologic drop in blood pressure during the first half of pregnancy may result in improved blood pressure control without drug treatment.[36,62] However, treatment may decrease uteroplacental blood flow and impair fetal development. Additionally, most of the increases in adverse fetal and maternal outcomes are caused by preeclampsia superimposed on chronic hypertension. Women should be monitored closely if treatment is discontinued, and therapy should be reinstituted if blood pressure exceeds 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic or if target-organ damage occurs. Alternatively, antihypertensive drugs may be continued (except for angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers) at the lowest effective dose. Use of diuretics (excluding spironolactone) is controversial but may be considered for chronic hypertension. Women with severe hypertension (blood pressure above 170 mmHg systolic or above 110 mmHg diastolic) should receive drug therapy to prevent occurrence of cerebrovascular hemorrhage or other target-organ damage.[37] Available evidence does not support superior efficacy of one agent versus another for blood pressure reduction.[34,36,37]

MENTAL HEALTH CONDITIONS

4 Psychiatric illness affects approximately 500,000 pregnancies each year.[63,64] Anxiety disorders, including panic disorder, obsessive–compulsive disorder, generalized anxiety disorder, posttraumatic stress disorder, social anxiety disorder, and phobias, can cause adverse maternal and fetal outcomes such as spontaneous abortion, preterm delivery, prolonged labor, and fetal distress.[63]

Depression occurs in 10% to 16% of pregnant women.[63,64] Maternal depression is associated with greater risk for premature birth, low birth weight, and fetal growth restriction. In addition to the potential impact of maternal depression on obstetric complications, untreated depression may have long-term implications for normal infant development.[63] Up to 6.4% of Americans have bipolar disorder, with men and women equally affected, but the incidence in pregnancy is unknown. Patients with bipolar disorder may be more likely to relapse during pregnancy, especially with rapid discontinuation of drug therapy.[64]

Schizophrenia occurs in 1% to 2% of women, however the incidence in pregnancy is unknown.[63,64] Drug therapy is usually necessary, although some women refuse treatment because of concerns about teratogenicity or paranoid or delusional thinking. Maternal schizophrenia is associated with increased risk of perinatal death, low birth weight, small-for-gestational-age infants, cardiovascular malformations, preterm delivery, stillbirth, and infant death.[63]

Nonpharmacologic therapies may be tried in pregnant women with psychiatric illnesses who fail to respond or inadequately respond to drug therapy and in those who refuse drug therapy. Cognitive behavioral therapy and interpersonal psychotherapy have been shown beneficial in the treatment of anxiety disorders and depression.[64] Light therapy has also been effective for treatment of seasonal depression. Electroconvulsive therapy is considered safe and effective treatment of major depression, bipolar disorder, and schizophrenia.

Because most psychotropic medications are used to treat more than one condition, the reader should refer to other sources for information about treatment of specific mental health diagnoses. In general, monotherapy is preferred over polytherapy even if higher doses are required.[64]

Neither the selective serotonin reuptake inhibitors (SSRIs) nor the tricyclic antidepressants are considered major teratogens.[63] The SSRIs are the drugs of first choice for several mental health conditions in the general population and are widely used by pregnant women. Data suggest that paroxetine may cause a 1.5- to 2-fold increased risk of cardiac malformations; this finding has not been replicated for other SSRIs. About 1 two 2 newborns per 1,000 develop persistent pulmonary hypertension. Infants exposed to SSRIs in utero after 20 weeks' gestation developed persistent pulmonary hypertension at a rate 6 times greater than the background rate; this finding needs further confirmation.[65] Overall, the absolute risk of major malformations with SSRIs is small; approximately 2 in 1,000 births are affected.[63] Use of SSRIs late in pregnancy can precipitate neonatal withdrawal symptoms consisting of irritability and difficulty with feeding and breathing. There are concerns about adverse effects in infants born to women who use SSRIs during pregnancy. However, women who stop taking antidepressants are more likely to relapse, and this can also have implications for the well-being of the infant.

Studies completed over 30 years ago showed an increased risk of oral clefts with diazepam use during pregnancy; these findings were not confirmed in a subsequent study.[63] A recent meta-analysis found the absolute risk of oral cleft changed from 6 cases to 7 cases

per 10,000 exposures (0.01%). Another large case-control study found no association between benzodiazepine use and congenital anomalies. Benzodiazepine use in the third trimester can cause infant sedation and withdrawal symptoms (i.e., restlessness, hypertonia, hyperreflexia, tremulousness, apnea, diarrhea, vomiting). "Floppy baby syndrome," consisting of low Apgar scores, hypothermia, poor muscle tone, feeding difficulties, and poor temperature adaptation, has also been described.

Mood stabilizers, such as lithium, lamotrigine, carbamazepine, and valproic acid, are often used to treat bipolar disorder.[63] The reader can find information related to the use of the seizure medications used for mood stabilization in the section on epilepsy.

Lithium's place in the treatment of bipolar disorder is controversial because of concerns about cardiovascular anomalies, especially Ebstein anomaly, in exposed infants.[63] A meta-analysis calculated that the relative risk for cardiac malformations was between 1.2 and 7.7 and for all congenital malformations was between 1.5 and 3. Stated differently, the risk for Ebstein anomaly after prenatal lithium exposure would rise from 1:20,000 to 1:1,000.[66] Other reported neonatal side effects include floppy baby syndrome, nephrogenic diabetes insipidus, hypoglycemia, cardiac arrhythmias, thyroid dysfunction, polyhydramnios, and premature delivery.[63,66] Lithium may cause lethargy, hypotonia, hypothermia, cyanosis, and changes in electrocardiogram in infants exposed through breast-feeding. If breastfeeding, the infant's lithium levels, thyroid function, and complete blood count should be monitored.

Chlorpromazine, haloperidol, and perphenazine have long histories of use during pregnancy, with no reported significant teratogenic effect.[63] Atypical antipsychotics are considered first-line treatment for schizophrenia because of their more favorable side-effect profiles and potential increased efficacy for treating negative symptoms compared with the older agents. However, use of atypical antipsychotics in pregnant women is controversial because of the limited data regarding teratogenic potential. Although olanzapine and clozapine have not been associated with increased risk for congenital malformations, they do cause weight gain and glucose intolerance, which have implications for poorer obstetric outcomes.[66] One study found a higher rate (10% vs. 2%) of low-birth-weight infants with olanzapine, clozapine, quetiapine, and risperidone compared with nonexposed infants.[63] At present, atypical antipsychotics do not appear to be safer than the typical agents.

THYROID DISORDERS

4 Hypothyroidism affects 0.1 to 0.3% of pregnancies.[40] Untreated hypothyroidism increases the risk of preeclampsia, premature birth, miscarriage, and growth restriction; impaired neurological development in the fetus may also occur. Causes of hypothyroidism include autoimmune diseases (e.g., Hashimoto thyroiditis), iodine deficiency (uncommon in the United States), and thyroid dysfunction following surgery or ablative therapy for previous hyperthyroidism. Thyroid replacement therapy should be instituted with levothyroxine 0.1 to 0.15 mg/day in hypothyroid patients; the goal is to attain normal thyrotropin concentration. Women receiving thyroid replacement therapy before pregnancy may have an increased dosage requirement during pregnancy; any dose change should follow thyroid function testing. Laboratory follow-up of thyrotropin concentrations and free T_4 should occur every 8 weeks.

Hyperthyroidism affects approximately 0.2% of pregnancies and is associated with fetal death, low birth weight, intrauterine growth restriction, and preeclampsia.[40] Graves disease accounts for 95% of hyperthyroidism in pregnancy. Therapy includes the thioamides (initial doses are propylthiouracil 100–150 mg or methimazole 5–20 mg). Either agent is given three times daily with dose reduction after becoming euthyroid. Surgery is reserved for the most severe cases. The risks of uncontrolled hyperthyroidism outweigh the risks of the thioamides. Iodine-131 is contraindicated because of the risk of thyroid damage in the fetus. The goal of therapy is to attain free thyroxine concentrations near the upper limit of normal to allow for dose minimization and to limit fetal or neonatal hypothyroidism.

LABOR AND DELIVERY

Management of the pregnant woman during the perinatal period often requires drug therapy for pain and for potential complications.

PRETERM LABOR

Preterm labor occurs when there are cervical changes and uterine contractions between 20 and 37 weeks' gestation.[67,68] Preterm birth is the leading cause of infant morbidity and mortality in the United States, with an incidence of 12.8%. Risk factors for preterm delivery include previous preterm delivery, infections, multiple gestation, poverty, nonwhite race, maternal complication factors (e.g., smoking and use of illicit drugs or alcohol), and uterine functional causes (e.g., incompetent cervix); previous history and prior second trimester loss confer a higher risk.[67,68]

No adequate tests are available for monitoring and preventing preterm labor. Monitoring of uterine activity along with intensive surveillance does not minimize risk.[68] The presence of fetal fibronectin, a glycoprotein found in cervicovaginal secretions, indicates a high risk of preterm birth. Cervical shortening is also associated with preterm delivery. Fetal fibronectin determinations and cervical ultrasound have not helped to prevent preterm labor but have been useful for their negative predictive value.[68]

Tocolytic Therapy

The purposes of tocolytic therapy are threefold: (a) postpone delivery long enough to allow for the maximum effect of antenatal steroid administration; (b) allow for transportation of the mother to a facility equipped to deal with high-risk deliveries; and (c) prolongation of pregnancy when there are underlying, self-limited conditions that can cause labor, such as pyelonephritis or abdominal surgery, that are unlikely to cause recurrent preterm labor.[68–70] Tocolytics have not reduced the number of premature deliveries. The criteria for starting tocolysis are regular uterine contractions with cervical change. Tocolytic therapy should not be used in cases of intrauterine fetal demise, a lethal fetal anomaly, intrauterine infection, fetal distress, severe preeclampsia, vaginal bleeding, or maternal hemodynamic instability.

Four classes of tocolytics are available in the United States: β-agonists, magnesium, calcium channel blockers, and NSAIDs.[71] All four therapies have similar effectiveness in prolonging pregnancy from 48 hours to 1 week. However, this prolongation of pregnancy was not associated with a statistically significant reduction in overall rates of respiratory distress syndrome or neonatal death.

The β-agonists terbutaline and ritodrine have been used for tocolytic therapy.[69] Ritodrine is no longer available in the United States. Relative to other agents, β-agonists have a higher incidence of maternal side effects, including hyperkalemia, arrhythmias, hyperglycemia, hypotension, and pulmonary edema. Recommended terbutaline doses range from 250 to 500 mcg subcutaneously every 3 to 4 hours.[70]

Intravenous magnesium sulfate has been used for tocolysis; however, a Cochrane review does not support its effectiveness.[72] Heterogeneity of study designs and results along with small treatment arms in included studies may partially explain this finding;

however, its use remains controversial.[69] The incidence of cerebral palsy is increased in premature infants. In one study, intravenous magnesium use (6 g load followed by 2 g per hour continuous infusion) decreased the occurrence of moderate or severe cerebral palsy.[73] Although not the primary end point, the study suggests that women at risk for imminent delivery (up to 34 weeks' gestation) should receive intravenous magnesium. Maternal side effects are rare but can include pulmonary edema. At toxic levels, hypotension, muscle paralysis, tetany, cardiac arrest, and respiratory depression may occur.[70] Magnesium undergoes renal excretion; dose adjustment is required in women with impaired renal function.

CURRENT CONTROVERSY

Intravenous magnesium sulfate is commonly used in the United States for tocolysis. Some advocate cessation of its use because a Cochrane review found no difference in preterm delivery in the 48 hours after administration and an increase in perinatal death.[69,72]

Nifedipine is associated with fewer side effects than magnesium or β-agonist therapy.[69] Several studies have suggested that calcium channel blockers are superior to β-agonists for prolonging labor. One concern with the use of nifedipine is its hypotensive effect and corresponding change in uteroplacental blood flow. However, a meta-analysis showed reduced neonatal morbidity with calcium channel blocker use. With the initial diagnosis of preterm labor, 5 to 10 mg nifedipine can be administered sublingually every 15 to 20 minutes for three doses. After patient stabilization, if no evidence of continuing cervical dilation is seen, 10 to 20 mg nifedipine can be administered orally every 4 to 6 hours for preterm contractions.[70]

Nonsteroidal antiinflammatory drugs such as indomethacin have been used for tocolysis.[69,70] Oral or rectal doses of 50 to 100 mg, followed by an oral dose of 25 to 50 mg every 6 hours, have been used. An increased rate of premature constriction of the ductus arteriosus has been noted in infants with indomethacin use after 32 weeks' gestation and with use exceeding 48 hours.[69] Indomethacin may be used when tocolysis is needed despite treatment with magnesium for neuroprotection because other agents, such as calcium channel blockers, can cause hypotension when administered concurrently with magnesium.

Other Drug Therapies for Preterm Labor Prevention

Infection is a potential cause of preterm labor. Antibiotics have been used, in addition to tocolytics and corticosteroids, to improve the outcome of preterm labor; however, a Cochrane review showed no reduction in the incidence of preterm delivery but a trend toward increased neonatal mortality. Therefore, routine use of antibiotics is not recommended. However, if a patient experiences preterm premature rupture of membranes (PPROM) before 34 weeks' gestation, prophylactic antibiotics should be initiated. The combination of initial intravenous therapy (48 hours) with ampicillin and erythromycin, followed by 5 days of oral therapy with the same antibiotics, decreased the likelihood of chorioamnionitis and delivery for 3 weeks. Additionally, a reduction in major morbidities (i.e., death, respiratory distress syndrome, early sepsis, severe intraventricular hemorrhage, and necrotizing enterocolitis) was demonstrated.[74]

Progesterone administration in the setting of prior preterm birth is much debated. Two large randomized, controlled trials produced significant findings. First, the administration of intramuscular 17-alpha-hydroxyprogesterone weekly (250 mg) starting between weeks 16 and 20 and continued through week 36 in high-risk women decreased the incidence of recurrent preterm birth.[75] The second study replicated the findings using vaginal progesterone suppositories (100 mg).[76] However, progesterone supplementation in women whose previous preterm birth occurred beyond 34 weeks produced similar rates of preterm delivery compared with placebo.[77] The American College of Obstetrics and Gynecology currently recommends that progesterone supplementation be limited to women with a singleton pregnancy and a previous history of spontaneous preterm birth.[78]

Antenatal Corticosteroids

4 Use of antenatal corticosteroids for fetal lung maturation to prevent respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely is supported by a Cochrane review.[79] The current clinical recommendation is to administer betamethasone 12 mg intramuscularly every 24 hours for two doses or dexamethasone 6 mg intramuscularly every 12 hours for four doses to pregnant women between 26 and 34 weeks' gestation who are at risk for preterm delivery within the next 7 days. Benefits from antenatal corticosteroids are believed to begin within 24 hours.

Salvage ("rescue") treatment is administered to women who are at risk of delivering within 7 days but who have received a previous course of therapy. The incidence of respiratory distress syndrome was lower with the administration of rescue steroids compared with placebo (41.4% with betamethasone vs. 61.6% with placebo).[80]

GROUP B *STREPTOCOCCUS* INFECTION

4 Maternal infection with group B *Streptococcus* (GBS) is associated with invasive disease in the newborn.[81,82] Women colonized with GBS have an increased risk for pregnancy loss, premature delivery, and transmission of the bacteria to the infant during delivery. Between 10% and 30% of pregnant women are colonized with GBS. The rate of invasive infection (defined as isolation of GBS from blood or other sterile body site excluding urine) in pregnant women is 0.12 per 1000 live births (range 0.11 to 0.14 per 1,000 births). The incidence of early-onset disease in neonates, although higher than in pregnant women, has declined steadily from 1.8 per 1,000 live births in 1990 to approximately 0.34 cases per 1,000 live births during 2003 to 2005. The consequences of neonatal infections include bacteremia, pneumonia, meningitis, and fatality in the newborn.[82] The case-fatality rate is approximately 4%.

Recommendations for prevention of GBS infection were updated in 2002.[82] Universal prenatal screening for GBS colonization is recommended. Antibiotics are given if the woman previously gave birth to an infant with invasive GBS disease or in the presence of GBS bacteriuria. All other pregnant women should have a vaginal/rectal culture at 35 to 37 weeks' gestation. If negative, antibiotics are not indicated. If a woman presents in labor and no screening information is available, antibiotics are given for fever greater than 100.4°F (38°C), membrane rupture at least 18 hours prior, or gestation under 37 weeks.

Penicillin G 5 million units given intravenously, followed by 2.5 million units given every 4 hours until delivery is the recommended treatment regimen.[82] Alternatively, ampicillin 2 g can be given intravenously, followed by 1 g every 4 hours. For women with penicillin allergy but not at risk for anaphylaxis, cefazolin 2 g intravenously, followed by 1 g every 8 hours, is recommended. In women at high risk for anaphylaxis, clindamycin 900 mg intravenously every 8 hours or erythromycin 500 mg intravenously every 6 hours is recommended. For penicillin-allergic women, GBS cultures should be sent for sensitivities. If resistant to clindamycin or erythromycin, vancomycin 1 g intravenously every 12 hours until delivery is appropriate.

CERVICAL RIPENING AND LABOR INDUCTION

Throughout gestation the cervix is closed and firm. During the last few weeks of pregnancy, the cervix softens and thins to facilitate labor.[83,84] This process is mediated by hormonal changes, including final mediation by prostaglandins E_2 and $F_2\alpha$, which increase collagenase activity in the cervix leading to thinning and dilation.

The rate of pregnancy induction ranges from 9.5% to 33.5%; the most common indications for induction are postdatism (beyond 42 weeks) and pregnancy-induced hypertension, which account for 80% of inductions.[83,84] Other reasons for induction include suspected fetal growth retardation, maternal hypertension, premature rupture of membranes with no active onset of labor, and social factors. Contraindications include placenta previa, oblique or transverse lie, pelvic structure abnormality, prolapsed umbilical cord, and active herpes. Concerns with induction of labor are ineffective labor and side effects, such as uterine hyperstimulation, that may adversely affect the infant and increase the likelihood of cesarean section.

Scoring systems have been used to determine the likelihood of successful labor induction. The Bishop scoring system is most commonly used and is based on five parameters: cervical dilation, cervical effacement (thinning), station of the baby's head, consistency of the cervix, and position of the cervix.[83,84] A Bishop score under 6 indicates the need for cervical ripening while a score above 8 corresponds to a likely successful vaginal delivery.

A number of nonpharmacologic methods are used for cervical ripening. Castor oil, hot baths, sexual intercourse, and nipple stimulation all have been suggested for labor induction.[83] Minimal evidence supports the efficacy of these methods. Use of a Foley catheter placed in an unfavorable cervix for ripening has been found as effective as prostaglandin E_2. Membrane stripping is safe and inexpensive.[83,84]

Prostaglandin E_2 analogs (e.g., dinoprostone [Prepidil gel, Cervidil vaginal insert]) are commonly used for cervical ripening. Prepidil 500 mcg is administered intracervically.[84] The dose may be repeated after 6 hours to a maximum of three doses in 24 hours. After administration, the patient remains supine for 30 minutes. Cervidil contains 10 mg dinoprostone with a slower, more constant release of medication than the gel. The insert is removed when labor begins or after 12 hours. Patients must be attached to a fetal heart rate monitor for the duration of Cervidil use and for 15 minutes after its removal.[83]

Misoprostol, a prostaglandin E_1 analog, is an effective and inexpensive drug for cervical ripening and labor induction.[84] Intravaginal administration of misoprostol is more effective than other prostaglandin agents and results in a shorter time to delivery. Oral misoprostol has been used successfully for cervical ripening and labor induction, but the evidence of safety is more extensive with intravaginal use. The most commonly encountered side effects are uterine hyperstimulation and meconium-stained amniotic fluid. Use of misoprostol is contraindicated in women with a previous uterine scar because of its association with uterine rupture, a catastrophic medical event.

CURRENT CONTROVERSY

Despite its efficacy and comparatively reasonable cost, some health systems have decided not to use misoprostol as an induction agent because of concerns about uterine rupture and lack of FDA indication for cervical ripening.[84]

Progesterone inhibits uterine contractions. Preliminary studies show that mifepristone, an antiprogesterone agent, compared with placebo results in a shorter time to delivery and fewer cesarean sections.[85] Limited information on fetal and maternal outcomes is available because of the small sample sizes.

Oxytocin is the most commonly used agent for labor induction after cervical ripening. By the end of pregnancy, the number of oxytocin receptors has increased by 300-fold.[83,84] A solution of 10 milliunits/mL is used for infusion. Oxytocin is effective in both low-dose (physiologic) and high-dose (pharmacologic) regimens.

LABOR ANALGESIA

In the first phase of labor, women perceive visceral pain caused by uterine contractions. Pain in the second phase of labor is associated with perineal stretching.[86]

Nonpharmacologic Approaches to Analgesia

Women who receive continuous support from nurses, midwives, childbirth educators, or doulas [laywomen trained in labor support], have fewer operative vaginal deliveries, cesarean deliveries, and requests for pain medication.[87] Warm water baths provide temporary pain relief but have not been shown to decrease the use of pharmacologic pain treatments. Intradermal injections of sterile water in the sacral area decrease back pain during labor for 45 to 120 minutes. However, requests for pain medication did not decrease in studies. Acupuncture has also been used for pain relief. Three randomized, controlled trials have shown that acupuncture decreases the need for analgesia, but more methodologically sound studies are needed. Use of audioanalgesia (music or white noise), relaxation and breathing techniques, application of heat and cold, aromatherapy, acupressure, and hypnosis have little to no evidence of effectiveness derived from randomized, controlled trials.

Pharmacologic Approaches to Labor Pain Management

The American College of Obstetricians and Gynecologists supports the concept that maternal request alone is a sufficient medical indication for labor analgesia.[88] The two main types of pharmacologic approaches in the United States are parenteral opioids and epidural analgesia.

Parenteral opioids are commonly used to alleviate labor pain.[89] In comparison with epidural analgesia, parenteral opioids have lower rates of oxytocin augmentation, result in shorter stages of labor, and require fewer instrumental deliveries.

Approximately 60% of women in the United States choose an epidural for pain relief during labor and report better pain relief than with other analgesic modalities.[89] With epidural analgesia, a catheter is introduced into the epidural space and an opioid and/or an anesthetic (e.g., fentanyl and/or bupivacaine) is administered. Combined spinal–epidural analgesia consists of injecting a single opioid bolus into the subarachnoid space to provide instant pain relief with additional use of a local anesthetic epidural. Patient-controlled epidural analgesia allows the patient to control the amount and timing of the anesthetic; it results in a lower total dose of local anesthetics used over the course of labor compared with continuous epidural infusions.[90]

Side effects of the regional anesthesia include hypotension, pruritus, and inability to void.[89] Epidural analgesia is associated with prolongation of the first and second stages of labor, higher numbers of instrumental deliveries, and maternal fever. A rare complication of epidural anesthesia is puncture of the subarachnoid space leading to a severe headache, which occurs in approximately 1% of women. Other complications include hypotension, nausea, vomiting, itching, and urinary retention. Low back pain has not been associated with the use of epidural analgesia.

POSTPARTUM HEMORRHAGE

The placenta is delivered after the delivery of the baby and is referred to as the third stage of labor. Postpartum hemorrhage is an obstetrical emergency and is a major cause of morbidity and mortality.[91] In the United States, the postpartum hemorrhage rate is approximately 1%–5% for vaginal deliveries.[92] The traditional definition of postpartum hemorrhage is more than 500 mL of blood within 24 hours of a vaginal delivery or 1,000 mL after a cesarean section; however, other definitions have also been suggested. Risk factors include retained placenta, failure to progress during the second stage of labor, placenta previa, placenta accreta, lacerations, instrumental delivery, large for gestational newborn, hypertensive disorders, induction of labor, augmentation of labor with oxytocin, prior history, obesity, and high parity.[93]

The most common cause of postpartum hemorrhage is uterine atony.[91,92] Initial management should include oxytocin. Early clamping and cutting of the umbilical cord as well as controlled traction of the cord also decrease the incidence.[91] Administration of a uterotonic medication (intramuscular oxytocin, ergotamine, or combination) before placental delivery and instituting active management of labor after all uncomplicated vaginal deliveries results in reduced maternal blood loss, fewer cases of postpartum hemorrhage, and less prolongation of the third stage of labor. Other uterotonic agents should be used if an inadequate response is attained with oxytocin alone. Methylergonovine, carboprost, misoprostol, and dinoprostone have all been used; less evidence is available for misoprostol and dinoprostone.

POSTPARTUM ISSUES

DRUG USE DURING LACTATION

5 Most drugs transfer into breast milk, but breast-feeding may be continued in most circumstances. Healthcare providers should encourage breast-feeding women who require medications to continue breast-feeding whenever possible. Medications that are contraindicated or require the mother to pump and discard milk are few.

A wide variety of benefits (health, nutritional, immunologic, psychological, economic, developmental, and social) are imparted by breast-feeding to infants, mothers, and the family.[94,95] Women should breast-feed exclusively for 6 months and continue until at least 12 months of age while other foods are introduced.[95] Healthy People 2010 set a target of 75% of neonates being breast-fed at the time of birth and 50% of infants being breast-fed at 6 months of age.

Most drugs reach breast milk through passive diffusion, but other drug-related factors influence drug transfer from maternal circulation into breast milk, including (a) degree of protein binding in maternal plasma, (b) molecular weight, (c) lipid solubility (and corresponding fat content of milk), (d) maternal plasma concentration, (e) drug half-life, and (f) drug pH.[94,96] The degree of protein binding to maternal plasma proteins is one of the most significant factors affecting drug transfer to breast milk; highly bound medications transfer in low amounts. Low-molecular-weight drugs passively diffuse into breast milk, but larger molecules are not likely to transfer in large amounts. Higher lipid solubility of drugs also increases the likelihood of transfer. Colostrum is secreted in the first couple of days after birth and has high quantities of immunoglobulins, maternal lymphocytes, and maternal macrophages. Compared with mature milk, colostrum is lower in fat content, so highly lipid soluble drugs achieve higher concentrations in mature milk. The higher the concentration of drug in the mother's serum, the higher the concentration will be in the breast milk. As the drug is metabolized and excreted by the mother, the mother's serum concentration drops, and drug in the breast milk may redistribute back into the mother's bloodstream. Maternal plasma pH is 7.4, while the pH of breast milk ranges between 6.8 and 7.[96] Weak bases are not ionized in the maternal circulation and easily transfer to breast milk. In the lower pH of breast milk, molecules become ionized and are less likely to diffuse back into maternal circulation ("ion trapping"). Likewise, drugs with longer half-lives are more likely to maintain higher levels in breast milk, resulting in greater exposure to the infant.

Infant-related factors may also influence the amount of drug ingested through breastfeeding.[94] Both the frequency of feedings and the amount of milk ingested are important considerations. Exclusively breast-fed infants are more likely to ingest larger amounts of drugs than older infants who receive other foods. Drugs unstable in gastric acid (aminoglycosides, omeprazole, heparin, insulin) are less likely to be absorbed by infants. Finally, infants may vary in their ability to metabolize and excrete ingested medication. Premature and full-term infants may not have full renal and liver function.

Strategies for reducing the risk to the infant include selection of medications that would be considered safe for use in the infant.[96] Drugs with shorter half-lives accumulate less, and those that are more protein bound do not cross into breast milk as well as those that are less protein bound. Drugs with lower oral bioavailability and lower lipid solubility are good choices. If the mother is using a once-daily medication, administration before the infant's longest sleep period may be advised to increase the interval to the next feeding. For medications taken multiple times per day, administration immediately after breast-feeding provides the longest interval for back diffusion of drug from the breast milk to the mother's serum. During short-term drug therapy, the mother can pump and discard milk to preserve her milk-producing capability if the medication is not considered compatible with breast-feeding.[94]

Industry-based research on transfer of drugs into breast milk is scarce.[94] Information from expert committees (e.g., American Academy of Pediatrics Committee on Drugs) and evidence-based textbooks or Web sites may be of assistance in providing reassurance regarding the safe use of medications in the lactating mother.

MASTITIS

Mastitis is inflammation in one breast.[97] It can be infectious or noninfectious; the most common cause is milk stasis. About 10% of women in the United States experience mastitis during the first 3 months postpartum. Signs and symptoms include breast tenderness, redness, warmth, and flulike symptoms.[98] Risk factors for developing mastitis include breast engorgement, plugged milk ducts, and cracked nipples.

Staphylococcus aureus is the most common bacterial cause of mastitis; *E. coli* and *Streptococcus* have also been implicated.[97,98] A 10- to 14-day course of antibiotics is usually given for treatment of mastitis; penicillinase-resistant penicillins (e.g., dicloxacillin, oxacillin) and cephalosporins (e.g., cephalexin) are frequently prescribed. Antiinflammatory drugs, such as ibuprofen, may provide some pain relief. Application of heat may also be helpful. Affected women should be counseled to continue breast-feeding from both breasts throughout treatment and to pump if breasts are not emptied completely with feedings.

POSTPARTUM DEPRESSION

Mood disorders in the postpartum period may include postpartum blues, postpartum depression, and postpartum psychosis.[99] Postpartum blues is common, usually affecting 15% to 85% of new mothers within the first 10 days of delivery, and generally does not require treatment. Symptoms include anxiety, anger, and sadness.

Postpartum psychosis is more severe but is rare, affecting less than 1% of new mothers.

Postpartum depression affects up to 15% of women.[99] Symptoms may develop during pregnancy or up to 6 months after delivery, although the strict definition for major depressive disorder after delivery specifies symptom occurrence within 1 month. Psychotherapy, including interpersonal psychotherapy, cognitive behavioral therapy, and group/family therapy, has been shown effective for treatment of postpartum depression.

In cases where pharmacotherapy is warranted, selection of medication with low transfer to breast milk is desirable. Sertraline is generally considered a first-line treatment because of its minimal transfer into breast milk and lack of reported adverse events in infants.[94,99] Paroxetine and nortriptyline are considered second-line.

CURRENT CONTROVERSY

Treatment of postpartum depression in the breast-feeding mother poses challenges since all antidepressants transfer into breast milk, and long-term effects on cognitive, behavioral, motor, and neurologic development are unknown.[99] Postpartum depression poses significant risks to both mother and infant. Benefits and risks of pharmacologic and nonpharmacologic therapy must be weighed in selecting treatments for women with postpartum depression.

RELACTATION

Adequate milk removal from the breast by breastfeeding or pumping is necessary to maintain or increase milk production.[100] Relactation is the process of increasing the breast milk supply for women who have failed lactogenesis II, who have inadequate milk production despite appropriate breastfeeding frequency or pumping, or who have weaned or never breast-fed after delivery. Lactation can also be induced in women who have not recently delivered a baby, such as adoptive mothers. The mainstay of therapy for this condition involves nipple stimulation either by the infant's nursing or by pumping of the breast with a mechanical pump or the hand.

Metoclopramide can be used for relactation if nonpharmacologic measures are ineffective because of its stimulation of prolactin secretion.[100] The most common dose is 10 mg orally three times daily for 7 to 14 days. Breast milk production can be increased up to 100% or more in women, although many of the studies have inadequate designs. Breast milk production may decrease after metoclopramide therapy is stopped, but production will continue if lactation has been established successfully.

CONCLUSION

Many women perceive a high inherent risk of birth defects with drug exposure during pregnancy. This perception, linked with a high rate of unplanned pregnancies, may create anxiety because of drug exposure prior to the discovery of pregnancy.

Some medications are considered safe for use in pregnancy because of frequent use with no apparent increase in the rate of congenital problems. In some cases, ensuring the health of the mother and the fetus will require selection or continuation of medications that have been associated with a higher risk of adverse effects to the fetus. In these instances, realistic information about the types and likelihood of adverse effects will aid the patient and her family in making decisions.

Healthcare providers who care for pregnant women must work in collaboration to seek, evaluate, and present the most contemporary and accurate information to their patients. Use of technology to access evidence-based resources, databases related to drug use in pregnancy, and primary and secondary literature may assist healthcare practitioners in accessing relevant medication information to manage drug therapy needs during pregnancy and lactation.

CHAPTER 88

Contraception

SARAH P. SHRADER, KELLY R. RAGUCCI, AND VANESSA A. DIAZ

KEY CONCEPTS

1. The attitude of the patient and sexual partner toward contraceptive methods, efficacy rate, the reliability of the patient in using the method correctly (which may affect the effectiveness of the method), noncontraceptive benefits, and the patient's ability to pay must be considered when selecting a contraceptive method.
2. Patient-specific factors (e.g., frequency of intercourse, age, smoking status, and concomitant diseases, or medications) must be evaluated when selecting a contraceptive method.
3. Adverse effects or difficulties using the chosen method should be monitored carefully and managed in consideration of patient-specific factors.
4. Accurate and timely counseling on the optimal use of the contraceptive method and strategies for minimizing sexually transmitted diseases must be provided to all patients when contraceptives are initiated and on an ongoing basis.
5. Emergency contraception may prevent pregnancy after unprotected intercourse or when regular contraceptive methods have failed.

Unintended pregnancy is a significant public health problem. In the United States, approximately 62 million women are of childbearing age, and approximately 6 million become pregnant each year.[1] The most recent data reveal that 31% of pregnancies are unintended, with the highest rates occurring in women aged 25 to 44 years (38%).[1] About half of all unintended pregnancies end in abortion, and half also occurred in sexually active couples who claimed they used some method of contraception.[2] If the goal of contraception—for pregnancies to be planned and desired—is to be realized, education on the use and efficacy of contraceptive methods must be improved.

ETIOLOGY AND PATHOPHYSIOLOGY

Comprehension of the hormonal regulation of the normal menstrual cycle is essential to understanding contraception in women (Fig. 88–1). The cycle of menstruation begins with menarche, usually around age 12 years, and continues to occur in nonpregnant women until menopause, usually around age 50 years. Factors such as race, body weight, medical conditions, and family history can affect the menstrual cycle.[3,4] The cycle includes the vaginal discharge of sloughed endometrium called *menses*. The menstrual cycle comprises three phases: follicular (or preovulatory), ovulatory, and luteal (or postovulatory).

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

THE MENSTRUAL CYCLE

The first day of menses is referred to as *day 1 of the menstrual cycle* and marks the beginning of the follicular phase.[3,4] The follicular phase continues until ovulation, which typically occurs on day 14. The time after ovulation is referred to as the *luteal phase*, which lasts until the beginning of the next menstrual cycle. The median menstrual cycle length is 28 days, but it can range from 21 to 40 days. Generally, variation in length is greatest in the follicular phase, particularly in the years immediately after menarche and before menopause.[4]

The menstrual cycle is influenced by the hormonal relationships among the hypothalamus, anterior pituitary, and ovaries.[3] The hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile fashion.[3,4] These GnRH bursts stimulate the anterior pituitary to secrete bursts of gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). FSH and LH direct events in the ovarian follicles that result in the production of a fertile ovum.

Follicular Phase

In the first 4 days of the menstrual cycle, FSH levels rise and allow the recruitment of a small group of follicles for continued growth and development (Fig. 88–1).[3,4] Between days 5 and 7, one follicle becomes dominant and later ruptures, releasing the oocyte. The dominant follicle develops increasing amounts of estradiol and inhibin, which cause a negative feedback on the hypothalamic secretion of GnRH and pituitary secretion of FSH, causing atresia of the remaining follicles recruited during the cycle.

Once the follicle has received FSH stimulation, it must receive continued FSH stimulation or it will die.[3,4] FSH allows the follicle to enlarge and synthesize estradiol, progesterone, and androgen. Estradiol stops the menstrual flow from the previous cycle, thickening the endometrial lining of the uterus to prepare it for embryonic implantation. Estrogen is responsible for increased production of thin, watery cervical mucus, which will enhance sperm transport during fertilization. FSH regulates the aromatase enzymes that convert androgens to estrogens in the follicle. If a follicle has insufficient aromatase, the follicle will not survive.

Ovulation

When estradiol levels remain elevated for a sustained period of time, the pituitary releases a midcycle LH surge (Fig. 88–1).[3,4] This LH surge stimulates the final stages of follicular maturation and

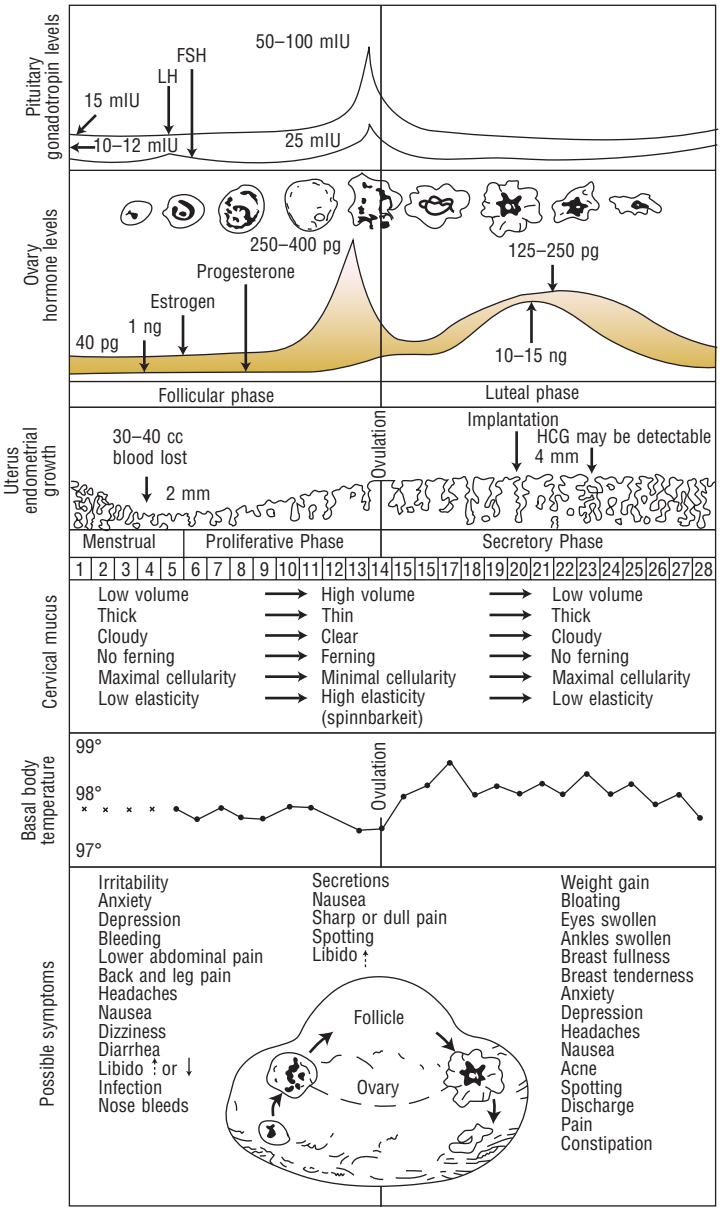

FIGURE 88-1. Menstrual cycle events, idealized 28-day cycle. (FSH, follicle-stimulating hormone; HCG, human chorionic gonadotropin, LH, luteinizing hormone.) *(From Hatcher et al.[4] This figure may be reproduced at no cost to the reader.)*

ovulation (follicular rupture and release of the oocyte). On average, ovulation occurs 24 to 36 hours after the estradiol peak and 10 to 16 hours after the LH peak. The LH surge, which occurs 28 to 32 hours before a follicle ruptures, is the most clinically useful predictor of approaching ovulation. After ovulation, the oocyte is released and travels to the fallopian tube, where it can be fertilized and transported to the uterus for embryonic implantation. Conception is most successful when intercourse takes place from 2 days before ovulation to the day of ovulation.

Luteal Phase

After rupture of the follicle and release of the ovum, the remaining luteinized follicles become the corpus luteum, which synthesizes androgen, estrogen, and progesterone (Fig. 88–1).[3,4] Progesterone helps to maintain the endometrial lining, which sustains the implanted embryo and maintains the pregnancy. It also inhibits GnRH and gonadotropin release, preventing the development of new follicles. If pregnancy occurs, human chorionic gonadotropin prevents regression of the corpus luteum and stimulates continued production of estrogen and progesterone secretion to maintain the pregnancy until the placenta is able to fulfill this role.

If fertilization or implantation does not occur, the corpus luteum degenerates, and progesterone production declines.[3,4] The life span of the corpus luteum depends on the continuous presence of small amounts of LH, and its average duration of function is 9 to 11 days. As progesterone levels decline, endometrial shedding (menstruation) occurs, and a new menstrual cycle begins. At the end of the luteal phase, when estrogen and progesterone levels are low, FSH levels start to rise, and follicular recruitment for the next cycle begins.

EPIDEMIOLOGY

Contraception implies the prevention of pregnancy following sexual intercourse by inhibiting viable sperm from coming into contact with a mature ovum (i.e., methods that act as barriers or prevent ovulation) or by preventing a fertilized ovum from implanting successfully in the endometrium (i.e., mechanisms that create an unfavorable uterine environment). These methods differ in their relative effectiveness, safety, and patient acceptability.[3–5]

The actual effectiveness of any contraceptive method is difficult to determine because many factors affect contraceptive failure.

A failure in patients who use the contraceptive agent properly is considered a method failure or perfect-use failure. It is also important to consider user failure or typical-use failure rates, which are usually higher because they take into account the user's ability to follow directions correctly and consistently.[3,4]

CLINICAL PRESENTATION

Most health maintenance annual visits should include assessment of and counseling about reproductive health. Clinicians may use this opportunity to provide contraception and educate patients on prevention of sexually transmitted diseases (STDs). Traditionally, hormonal contraception is provided subsequent to breast and pelvic examinations. However, the need for the physical examination may delay access to contraception, resulting in unintended pregnancies. In addition, requiring breast and pelvic examinations prior to prescription of hormonal contraception reinforces the incorrect perception that these methods of contraceptives are harmful. Therefore, the American Congress of Obstetrics and Gynecology (ACOG) and other national organizations allow provision of hormonal contraception after a simple medical history and blood pressure measurement.[6] Other preventive measures, such as pelvic and breast examinations, provision of the human papillomavirus vaccine, and screening for cervical neoplasia can be accomplished during routine annual office visits.[6–9]

TREATMENT

DESIRED OUTCOME

The obvious goal of treatment with all methods of contraception is to prevent pregnancy. However, many health benefits are associated with contraceptive methods, including prevention of STDs (with condoms), improvements in menstrual cycle regularity (with hormonal contraceptives), improvements in certain health conditions (with oral contraceptives [OCs]), and management of perimenopause.[3]

NONPHARMACOLOGIC THERAPY

Periodic Abstinence

1 2 Motivated couples may use the abstinence (rhythm) method of contraception, avoiding sexual intercourse during the days of the menstrual cycle when conception is likely to occur. Physiologic changes, such as basal body temperature and cervical mucus are used during each cycle to determine the fertile period. The major drawbacks are the relatively high pregnancy rates and avoidance of intercourse for several days during each menstrual cycle.[3,4]

Barrier Techniques

1 2 The effectiveness of barrier methods depends almost exclusively on motivation to use them consistently and correctly.[3,4] These methods include condoms, diaphragms, cervical caps, and sponges (Table 88–1). A major disadvantage is higher failure rates than most hormonal contraceptives; thus, provision of counseling and an advanced prescription for emergency contraception (EC) are recommended for all patients using barrier methods as their primary means of contraception.

Condoms create a mechanical barrier, preventing direct contact of the vagina with semen, genital lesions, and infectious secretions.[3,4] Most condoms in the United States are made of latex, which is impermeable to viruses. A small proportion are made from lamb intestine, which is not impermeable to viruses. Synthetic condoms manufactured from polyurethane are another option, these condoms are latex-free and do protect against viruses. Condoms are used worldwide as protection from STDs including human immunodeficiency virus (HIV). When condoms are used in conjunction with any other barrier method, their effectiveness theoretically approaches 98%. Spillage of semen or perforation and tearing of the condom can occur, but proper use minimizes these problems.[4] Mineral oil–based vaginal drug formulations (e.g., Cleocin, Premarin, and Monistat), lotions, or lubricants can decrease the barrier strength of latex, thus making water-soluble lubricants (e.g., Astroglide, K-Y Jelly) preferable.[4] Condoms with spermicides are no longer recommended because they provide no additional protection against pregnancy or STDs and may increase vulnerability to HIV.[4]

The female condom (FC, formerly Reality brand) is a prelubricated, loose-fitting polyurethane sheath, closed at one end, with flexible rings at both ends.[3,4] Properly positioned, the ring at the closed end covers the cervix, and the sheath lines the walls of the vagina. The outer ring remains outside the vagina, covering the labia. The pregnancy rate is reported to be 21% in the first year of typical use. Male and female condoms should not be used together, as slippage and device displacement may occur.

The diaphragm, a reusable dome-shaped rubber cap with a flexible rim that is inserted vaginally, fits over the cervix in order to decrease access of sperm to the ovum. The diaphragm requires a prescription from a physician who has fitted the patient for the correct size.[3,4] Its effectiveness depends on its function as a barrier and on the spermicidal cream or jelly placed in the diaphragm before insertion. The diaphragm may be inserted up to 6 hours before intercourse and must be left in place for at least 6 hours afterward. However, leaving it in place for more than 24 hours is not recommended due to the potential for toxic shock syndrome. With subsequent acts of intercourse, the diaphragm should be left in place, and a condom should be used for additional protection.[3]

The cervical cap is a soft, deep cup with a firm round rim that is smaller than a diaphragm and fits over the cervix like a thimble.[3,4] Currently, two latex-free cervical caps are available by prescription in the United States: the FemCap and the Lea's Shield.[3] The FemCap is available in three sizes and should be filled with spermicide prior to insertion.[3,4] It is held in place against the cervix until the cap is removed. The Lea's Shield is available in only one size and is held in place by the vaginal wall; therefore, cervical size is not a factor.[3] Both caps can be inserted 6 hours prior to intercourse and should not be removed for at least 6 hours after intercourse. They may remain in place for multiple episodes of intercourse without adding more spermicide but should not be worn for more than 48 hours at a time to reduce the risk of toxic shock syndrome. Failure rates are higher than with other methods. Some studies have shown an increased risk of cervical dysplasia, so users must have a repeat Papanicolaou (Pap) smear 3 months after starting to use a cervical cap.[3] Diaphragms and cervical caps do not protect against some STDS including HIV, thus condoms should also be used.

PHARMACOLOGIC THERAPY

Spermicides

1 2 Spermicides, most of which contain nonoxynol-9, are chemical surfactants that destroy sperm cell walls and act as barriers that prevent sperm from entering the cervical os.[4] They are available as creams, films, foams, gels, suppositories, sponges, and tablets.[3,4] Spermicides offer no protection against STDs. In fact, when used frequently (more than 2 times per day), nonoxynol-9 may increase the risk of transmission of HIV by causing small disruptions in the

TABLE 88-1 Comparison of Methods of Nonhormonal Contraception

Method	Absolute Contraindications	Advantages	Disadvantages	Percentage of Women with Pregnancy[a]	
				Perfect Use	*Typical Use*
Condoms, male	Allergy to latex or rubber	Inexpensive STD protection, including HIV (latex only)	High user failure rate Poor acceptance Possibility of breakage Efficacy decreased by oil-based lubricants Possible allergic reactions to latex in either partner	2	15
Condoms, female	Allergy to polyurethane History of TSS	Can be inserted just before intercourse or ahead of time STD protection, including HIV	High user failure rate Dislike ring hanging outside vagina Cumbersome	5	21
Diaphragm with spermicide	Allergy to latex, rubber, or spermicide Recurrent UTIs History of TSS Abnormal gynecologic anatomy	Low cost Decreased incidence of cervical neoplasia Some protection against STDs	High user failure rate Decreased efficacy with increased frequency of intercourse Increased incidence of vaginal yeast UTIs, TSS Efficacy affected by oil-based lubricants Cervical irritation	6	16
Cervical cap (FemCap, Lea's Shield)	Allergy to spermicide History of TSS Abnormal gynecologic anatomy Abnormal Papanicolaou smear	Low cost Latex-free Some protection against STDs FemCap reusable for up to 2 years	High user failure rate Decreased efficacy with parity Cannot be used during menses	9	16[b]
Spermicides alone	Allergy to spermicide	Inexpensive	High user failure rate Must be reapplied before each act of intercourse May enhance HIV transmission No protection against STDs	18	29
Sponge (Today)	Allergy to spermicide Recurrent UTIs History of TSS Abnormal gynecologic anatomy	Inexpensive	High user failure rate Decreased efficacy with parity Cannot be used during menses No protection against STDs	9[c]	16[d]

HIV, human immunodeficiency virus; STD, sexually transmitted disease; TSS, toxic shock syndrome; UTI, urinary tract infection.
[a]Failure rates in the United States during first year of use.
[b]Failure rate with FemCap reported to be 29% per package insert.
[c]Failure rate with Today sponge reported to be 20% in parous women.
[d]Failure rate with Today sponge reported to be 32% in parous women.
Data from Hatcher and Nelson,[4] and Dickey.[5]

vaginal epithelium.[10,11] The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) do not promote products containing nonoxynol-9 for protection against STDs. Women at high risk for HIV infection or who are HIV infected should not use spermicides.[3,12,13]

Spermicide-Implanted Barrier Techniques

1 2 The vaginal contraceptive sponge (Today) contains 1 g of the spermicide nonoxynol-9.[4] It has a concave dimple on one side to fit over the cervix and a loop on the other side to facilitate removal. After being moistened with water, the sponge is inserted into the vagina up to 6 hours before intercourse. The sponge provides protection for 24 hours, regardless of the frequency of intercourse during this time. After intercourse, the sponge must be left in place for at least 6 hours before removal and should not be left in place for more than 24 to 30 hours to reduce the risk of toxic shock syndrome. Sponges should not be reused, after removal they should be discarded. The sponge comes in one size and is available over the counter (OTC).[4]

Hormonal Contraception

Hormonal contraceptives contain a combination of estrogen and progestin or a progestin alone. Oral contraceptive preparations first became available in the 1960s, but options have expanded to include a transdermal patch, a vaginal contraceptive ring, and long-acting injectable, implantable, and intrauterine contraceptives.

Combined hormonal contraceptives (CHCs) work primarily before fertilization to prevent conception. Progestins provide most of the contraceptive effect, by thickening cervical mucus to prevent sperm penetration, slowing tubal motility and delaying sperm transport, and inducing endometrial atrophy. Progestins block the LH surge, therefore inhibiting ovulation. Estrogens suppress FSH release from the pituitary, which may contribute to blocking the LH surge and preventing ovulation. However, the primary role of estrogen in hormonal contraceptives is to stabilize the endometrial lining and provide cycle control.[3–5]

Estrogens Two synthetic estrogens found in hormonal contraceptives available in the United States are ethinyl estradiol (EE) and mestranol. Mestranol, must be converted by the liver to EE before it is pharmacologically active and is 50% less potent than EE.[3–5] Most combined OCs, transdermal patch, and vaginal ring contain estrogen at doses of 20 to 50 mcg of EE.[4]

Progestins A variety of progestins are available in the United States and they vary in their progestational activity and differ with respect to inherent estrogenic, antiestrogenic, and androgenic effects.[3–5] Estrogenic and antiestrogenic properties are secondary to the extent of progestins' metabolism to estrogenic substances. Androgenic activity is dependent upon two variables: the presence of sex hormone (testosterone) binding globulin (SHBG-TBG) and

the androgen:progesterone activity ratio. If the amount of SHBG-TBG is decreased, free testosterone levels increase and androgenic side effects are more prominent.[5]

Considerations with Combined Hormonal Contraceptive Use. 1 When selecting a CHC, clinicians are challenged by weighing the benefits and risks associated with the many formulations available. The clinician must determine if the form of contraception is appropriate based upon the patient's lifestyle and potential adherence. A complete medical examination and Pap smear are not necessary before a CHC is prescribed. A medical history and blood pressure measurement should be obtained before prescribing a CHC, along with a discussion of the benefits, risks, and adverse effects with each patient.[3–5,14–16] For example, OCs are associated with noncontraceptive benefits, including relief from menstruation-related problems (e.g., decreased menstrual cramps, decreased ovulatory pain [mittelschmerz], and decreased menstrual blood loss), improvement in menstrual regularity and decreased iron deficiency anemia. Women who take combination OCs have a reduced risk of ovarian and endometrial cancer. There is a 50% reduction in risk in women who have used OCs for 5 years or more, and protection may persist for more than 10 years post-use. Combination OCs may also reduce the risk of ovarian cysts, ectopic pregnancy, pelvic inflammatory disease, endometriosis, uterine fibroids, and benign breast disease. The CHC transdermal patch and vaginal ring are other combined hormonal options that may be more convenient for women than taking a tablet each day.

2 3 Adverse effects may hinder adherence and therefore efficacy, so they should be discussed prior to initiating a hormonal contraceptive agent (Table 88–2). Excessive or deficient amounts of estrogen and progestin are related to the most common adverse effects.[3–5] The CHC vaginal ring may be uncomfortable for some women and cause vaginal discharge. The CHC patch may cause irritation and now has information added to product labeling regarding the increased potential for thromboembolism.

An important concern regarding the use of CHCs is the lack of protection against STDs. Because of their high efficacy in preventing pregnancy, patients may choose not to use condoms. In addition to public health awareness, clinicians must encourage patients to use condoms for prevention of STDs. OCs have an extensive history of safety concerns, which traditionally were related to high dose estrogen tablets. To replace the traditional absolute and relative contraindications to the use of OCs, the WHO developed a graded list of precautions for clinicians to consider when initiating CHCs (Table 88–3).[4,12,13]

In addition to the WHO precautions, the ACOG provides information for clinicians to use when selecting CHCs for women with coexisting medical conditions.[17] Overall, the health risks associated with pregnancy, the specific health risks associated with CHCs and the noncontraceptive benefits of CHCs should be factored into risk-to-benefit considerations.

Women Older Than 35 Years. Use of CHC in women older than 35 years of age is controversial. Older women, especially women in their 40s retain a level of fertility even in the perimenopausal state and should use contraception to prevent pregnancy. Formulations with lower doses of estrogen (less than 30 mcg) have increased the use of CHCs in these women. In addition to the benefit of pregnancy prevention, they may improve or decrease the chance of developing perimenopausal and menopausal symptoms and increase bone mineral density (BMD). However, the benefits of using CHCs must be weighed against the risks in women older than 35. The increased risk of cardiovascular disease and venous thromboembolism (VTE) should be considered especially in perimenopausal women older than 40. Older data suggests an increased risk of myocardial infarction (MI) in older women using CHCs, although many women in these studies were current smokers and used older formulations containing higher doses (greater than 50 mcg) of estrogen. More recent data does not support the increased risk of cardiovascular disease when low dose formulations of CHCs are used in healthy, non-obese women. Other concerns include the increased risk of ischemic stroke in women with migraines and the increased risk of breast cancer in older women.[4,16–18]

The risks and benefits of using CHCs in women greater than 35 must be considered on an individual basis. The ACOG and WHO recommend that use of CHCs (with less than 50 mcg of estrogen) may be considered in healthy nonsmoking women. Furthermore, they recommend against the use of CHCs in women older than 35 with migraine (with or without aura), hypertension, dyslipidemia, current smoker, and type 1 or type 2 diabetes mellitus.[13,17]

Smoking. In early studies, OCs with 50 mcg EE or more were associated with MI in women who smoked cigarettes.[4,14,16,17] U.S. case-control studies have found that both nonsmoking and smoking women, regardless of age, taking OCs with less than 50 mcg EE did not have an increased risk of MI or stroke. However, these studies included few women older than 35 years who were smokers. European studies, with a higher population of older smoking women, demonstrated an increased risk of MI in this population.

TABLE 88-2 Adverse Effects of Combined Hormonal Contraception and Their Management[a]

Adverse Effects	Management
Estrogen excess	
Nausea, breast tenderness, headaches, cyclic weight gain due to fluid retention	Decrease estrogen content in CHC Consider progestin-only methods or IUD
Dysmenorrhea, menorrhagia, uterine fibroid growth	Decrease estrogen content in CHC Consider extended-cycle or continuous regimen OC Consider progestin-only methods or IUD NSAIDs for dysmenorrhea
Estrogen deficiency	
Vasomotor symptoms, nervousness, decreased libido	Increase estrogen content in CHC
Early-cycle (days 1–9) breakthrough bleeding and spotting	Increase estrogen content in CHC
Absence of withdrawal bleeding (amenorrhea)	Exclude pregnancy Increase estrogen content in CHC if menses is desired Continue current CHC if amenorrhea acceptable
Progestin excess	
Increased appetite, weight gain, bloating, constipation	Decrease progestin content in CHC
Acne, oily skin, hirsutism	Decrease progestin content in CHC Choose less androgenic progestin in CHC
Depression, fatigue, irritability	Decrease progestin content in CHC
Progestin deficiency	
Dysmenorrhea, menorrhagia	Increase progestin content in CHC Consider extended-cycle or continuous regimen OC Consider progestin-only methods or IUD NSAIDs for dysmenorrhea
Late-cycle (days 10–21) breakthrough bleeding and spotting	Increase progestin content in CHC

CHC, combined hormonal contraceptive; IUD, intrauterine device; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive.

[a]CHC regimens should be continued for at least 3 months before adjustments are made based on adverse effects.

Data from Hatcher and Nelson,[4] and Dickey.[5]

TABLE 88-3 World Health Organization Precautions in the Provision of Combined Hormonal Contraceptives (CHCs)

Category 4: Refrain from providing CHCs to women with the following diagnoses

- Thrombophlebitis or thromboembolic disorder, or a history of these conditions
- Cerebrovascular disease, coronary artery disease, peripheral vascular disease
- Valvular heart disease with thrombogenic complications (e.g., pulmonary hypertension, atrial fibrillation, history of endocarditis)
- Diabetes with vascular involvement (e.g., nephropathy, retinopathy, neuropathy, other vascular disease or diabetes >20 years' duration)
- Migraine headaches with focal aura
- Uncontrolled hypertension (≥160 mm Hg systolic or ≥90 mm Hg diastolic)
- Major surgery with prolonged immobilization
- Thrombogenic mutations (e.g., factor V Leiden, protein C or S deficiency, antithrombin III deficiency, prothrombin deficiency)
- Breast cancer
- Acute or chronic hepatocellular disease with abnormal liver function, cirrhosis, hepatic adenomas, or hepatic carcinomas
- Age >35 years and currently smoking ≥15 cigarettes per day
- Known or suspected pregnancy
- Breastfeeding women <6 weeks postpartum

Category 3: Conditions may be adversely impacted by CHCs, and the risks generally outweigh the benefits; providers should exercise caution if combined CHCs are used in these situations, and patients should be carefully monitored for adverse effects

- Multiple risk factors for arterial cardiovascular disease
- Known hyperlipidemia
- Migraine headache without aura in women ≥35 years old
- History of hypertension (140–159 mm Hg systolic or 90–99 mm Hg diastolic)
- History of cancer, but no evidence of current disease for 5 years
- Cirrhosis, mild and compensated
- Symptomatic gallbladder disease
- Cholestatic jaundice with prior pill use
- Age >35 years and currently smoking <15 cigarettes per day
- Postpartum <21 days, not breastfeeding
- Breast-feeding women 6 weeks to 6 months postpartum
- Commonly used drugs that induce liver enzymes (rifampin, phenytoin, carbamazepine, barbiturates, primidone, topiramate) and reduce efficacy of CHC

Category 2: Some conditions may trigger potential concerns with CHCs, but benefits usually outweigh risks

- Family history of thromboembolism
- Superficial thrombophlebitis
- Uncomplicated valvular heart disease
- Diabetes without vascular disease
- Sickle cell disease
- Migraine headaches without aura in women <35 years old
- Hypertension during pregnancy, resolved postpartum
- Major surgery without prolonged immobilization
- Gallbladder disease (symptomatic and treated by cholecystectomy or asymptomatic)
- Cholestatic jaundice of pregnancy
- Undiagnosed breast mass
- Undiagnosed abnormal genital bleeding
- Cervical intraepithelial neoplasia or cervical cancer
- Obesity (body mass index ≥30 kg/m^2)
- Age <35 years and currently smoking
- Breastfeeding women ≥6 months postpartum
- Age ≥40 years
- Drugs that may induce metabolism of CHC and reduce efficacy (griseofulvin, antiretroviral therapy)

Category 1: Do not restrict use of combined oral contraceptives for the following conditions

- Varicose veins
- History of gestational diabetes
- Nonmigrainous headaches
- Thyroid disease
- Thalassemia
- Iron deficiency anemia
- Depression
- Epilepsy
- Infectious diseases (HIV, schistosomiasis, tuberculosis, malaria)
- Minor surgery without immobilization
- Benign ovarian tumors
- Endometriosis
- Irregular or heavy vaginal bleeding, severe dysmenorrhea
- Sexually transmitted diseases
- Uterine fibroids
- Pelvic inflammatory disease
- Endometrial cancer
- Ovarian cancer
- History of pelvic surgery
- Trophoblast disease
- History of ectopic pregnancy
- Postabortion
- Postpartum women ≥21 weeks, not breastfeeding
- Menarche to 40 years of age
- Drug interactions with antibiotics other than rifampin and griseofulvin

CHC, combined hormonal contraception; HIV, human immunodeficiency virus.
Data from Hatcher and Nelson,[4] Dickey,[5] World Health Organization.[12,13]

Therefore, practitioners should prescribe CHC with caution, if at all, to women older than 35 years who smoke. The WHO precautions further state that smoking 15 or more cigarettes per day by women in this age group is a contraindication to CHC, and that the risks generally outweigh the benefits of CHC in those who smoke fewer than 15 cigarettes per day.[13] Progestin-only contraceptive methods should be considered for women in this group.

Hypertension. CHCs can cause small increases (i.e., 6–8 mm Hg) in blood pressure, regardless of estrogen dosage.[4,14,16,17] This has been documented in both normotensive and mildly hypertensive women given a 30 mcg EE OC. In case-control studies of women with hypertension, OCs have been associated with an increased risk of MI and stroke. Use of low dose CHC is acceptable in women younger than 35 years with well-controlled and frequently monitored hypertension. If a CHC-related increase in blood pressure occurs, discontinuing the CHC usually restores blood pressure to pretreatment values within 3 to 6 months.[4] Hypertensive women who have end-organ vascular disease or who smoke should not use CHCs. Women with hypertension who are taking potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or aldosterone antagonists may have increased serum potassium concentrations if they are also using an OC containing drospirenone, which has antialdosterone properties.[4]

Dyslipidemia. Generally, synthetic progestins adversely affect lipid metabolism by decreasing high-density lipoprotein (HDL) and increasing low-density lipoprotein (LDL).[4,16,17] Estrogens tend to have more beneficial effects by enhancing removal of LDL and increasing HDL levels. Estrogens may moderately increase triglycerides. As a net result, most low-dose CHCs have no significant impact on HDL, LDL, triglycerides, or total cholesterol. CHCs containing more androgenic progestins (e.g., levonorgestrel) may result in lower HDL levels in some patients. Although the lipid effects of CHCs theoretically can influence cardiovascular risk, the mechanism of increased cardiovascular disease in CHC users is believed to be due to thromboembolic and thrombotic changes, not athero-

sclerosis. Women with controlled dyslipidemia can use low dose CHCs, although periodic fasting lipid profiles are recommended. Women with uncontrolled dyslipidemia (LDL greater than 160 mg/dL [4.14 mmol/L], HDL less than 35 mg/dL [0.91 mmol/L], triglycerides greater than 250 mg/dL [2.83 mmol/L]) and additional risk factors (e.g., coronary artery disease, diabetes, hypertension, smoking, or positive family history) should use an alternative method of contraception.

Diabetes. Any effect of CHCs on carbohydrate and lipid metabolism is thought to be due to the progestin component.[4,17] However, with the exception of some levonorgestrel-containing products, formulations containing low doses of progestins do not significantly alter insulin, glucose, or glucagon release after a glucose load in healthy women or in those with a history of gestational diabetes. The new progestins are believed to have little, if any, effect on carbohydrate metabolism. CHCs do not appear to alter the hemoglobin A_{1c} values or accelerate the development of microvascular complications in women with type 1 diabetes. In the Nurses' Health Study, women who used OCs did not demonstrate any increased risk of developing type 2 diabetes.[17] Therefore, nonsmoking women younger than 35 years with diabetes but no associated vascular disease can safely use CHCs. Diabetic women with vascular disease (e.g., nephropathy, retinopathy, neuropathy, or other vascular disease or diabetes of more than 20 years' duration) should not use CHCs.

Migraine Headaches. Women with migraine headaches may experience a decreased or an increased frequency of migraine headaches when using CHCs.[4,14,16,17,19] Headaches may even occur during the hormone-free interval. Studies have demonstrated a higher risk of stroke in women experiencing migraine with aura compared to women with simple migraine. In population-based studies, the risk of stroke in women with migraines has been elevated twofold to threefold. However, given the low absolute risk of stroke in young women (age less than 35 years), the ACOG recommends considering CHCs in healthy, nonsmoking women with migraine headaches without aura.[17] Women of any age who have migraine with aura should not use CHC. Women who develop migraines (with or without aura) while receiving CHC should discontinue use and consider a progestin-only option.

Breast Cancer. Worldwide epidemiologic data from 54 studies in 25 countries (many of which studied high dose OCs) were collected to assess the relationship between OCs and breast cancer.[17] Overall, investigators noted a small increased risk of breast cancer associated with current or recent use, but OCs did not further increase risk in women with a history of benign breast disease or a family history of breast cancer. A more recent U.S.–based case-control study found no association between overall breast cancer and current or past OC use.[17] This study also found no association between depomedroxyprogesterone acetate (DMPA) and breast cancer. Although some studies have found differences in risk of breast cancer based on the presence of *BRCA1* and *BRCA2* mutations, the most recent cohort study found no association with low dose OCs and the presence of either mutation. The choice to use CHCs should not be affected by the presence of benign breast disease or a family history of breast cancer with either mutation. The WHO precautions state that women with a recent personal history of breast cancer should not use CHCs, but that CHCs can be considered in women without evidence of disease for 5 years.[13]

Thromboembolism. Estrogens increase hepatic production of factor VII, factor X, and fibrinogen in the coagulation cascade, therefore increasing the risk of thromboembolic events (deep vein thrombosis, pulmonary embolism). These risks are increased in women who have underlying hypercoagulable states (e.g., deficiencies in antithrombin III, protein C, and protein S; factor V Leiden mutations, prothrombin G2010 A mutations) or who have acquired conditions (e.g., obesity, pregnancy, immobility, trauma, surgery, and certain malignancies) that predispose them to coagulation abnormalities.[4,14,16,17,20] In U.S. case-control studies, the risk of VTE in women currently using low dose OCs (less than 50 mcg EE) was 4 times the risk in nonusers.[4,16,17] However, this risk is less than the risk of VTE incurred during pregnancy. OCs containing desogestrel have been associated with a 1.7 to 19 times higher risk of VTE than OCs containing levonorgestrel. Some clinicians argue that this difference reflects preferential prescribing of the newer, and perceived safer, progestin products for women at greater risk for VTE. Estrogen exposure in women using transdermal CHC may be greater than that in women taking OCs or using the vaginal ring over time, but the absolute risk of VTE in this population is unknown. Therefore, CHCs are contraindicated in women with a history of thromboembolic events and in those at risk due to prolonged immobilization with major surgery unless they are currently taking anticoagulants. Women with familial coagulopathies are at particular risk during pregnancy, given the risk of VTE and of fetal exposure to warfarin. CHCs reduce menstrual blood loss and are safe for use by women with appropriate anticoagulation. EC has not been associated with an increased risk of thromboembolic events.

Obesity. The prevalence of obesity continues to rise each year among all age groups including women of childbearing age. It has been hypothesized that women with increased body weight have increased basal metabolic rates and induction of hepatic enzymes, leading to increased hormonal clearance and decreased serum concentrations of hormonal contraceptives. In addition, women who are obese have more adipose tissue, increasing hormonal sequestration, and decreased free hormone serum concentrations resulting in lower efficacy.[4,17] In one recent case-control study, the odds ratio for pregnancy was 1.58 (CI, 1.11-2.24) and 1.72 (CI, 1.04-2.82) in women with a body mass index greater than 27 kg/m^2 or greater than 32 kg/m^2, respectively. The authors concluded that this association translates to an additional 2 to 4 pregnancies per 100 woman-years of use in overweight or obese users.[21] This decreased efficacy may be a particular issue with the low dose OCs. Along these same lines, ACOG recommends that the transdermal contraceptive patch should not be used as a first-line option in women weighing greater than 90 kg (198 lbs).[17] It is important to note, however, that the overall risk of decreased efficacy is relatively small when compared to the alternative of increased pregnancy rates when women do not use contraception. It should be noted that increased pregnancy rates have not been demonstrated in obese women using DMPA or the levonorgestrel IUD.

Obese women are also at risk of VTE. In a few population-based case-control studies, obesity (defined as a BMI greater than or equal to 30 kg/m^2) was associated with an increased risk of VTE when all other factors, including age and estrogen dosage, were controlled. The mechanism to support the evidence is unclear. Women should be counseled on the risk and consider alternative contraceptive methods on an individual basis.

Systemic Lupus Erythematosus. Contraception is important in women with systemic lupus erythematosus (SLE) because the risks associated with pregnancy are high in this population. Historically, clinicians have thought that CHCs exacerbated the symptoms of SLE.[4,17,22] However, trials have shown that OCs do not increase the risk of flare among women with stable SLE and without antiphospholipid/anticardiolipin antibodies. Because 25% of women with SLE who become pregnant choose to terminate the pregnancy, effective contraception is essential for these patients. CHCs should be avoided in women with SLE and antiphospholipid antibodies or vascular complications; progestin-only contraceptives can be used in this situation.

Sickle Cell Disease. Two controlled trials have demonstrated a reduction in risk of vasoocclusive crises in women with sickle cell disease using DMPA as the method of contraception.[17] Theoretical concerns about the effects of CHCs on platelet activation and red cell deformity, for example, led clinicians to avoid their use in women with sickle cell disease. Because pregnancy carries such a high risk in this population, contraception with DMPA should be considered.

Oral Contraceptives 1 2 With perfect-use, OCs have a 99% efficacy rate, but with typical-use up to 8% of users may become pregnant.[3–5] The OCs currently available are modifications of the original products introduced in the 1960s and contain significantly less estrogen and progestin.[3–5,14] High-dose formulations were associated with vascular and embolic events, cancers, and significant side effects, but reductions in hormone doses have been associated with fewer complications.

Monophasic OCs contain the same amounts of estrogen and progestin for 21 days, followed by 7-day placebo phase. Biphasic and triphasic pills contain variable amounts of estrogen and progestin for 21 days, also followed by a 7-day placebo phase. There are no published data demonstrating increased safety or significant differences in bleeding patterns with the multiphasic tablets compared to monophasic tablets.[3,4,14,23,24] Extended-cycle tablets and continuous combination regimens may offer some benefits for patients in terms of side effects and convenience. One particular extended-cycle OC increases the number of hormone-containing pills from 21 to 84 days, followed by a 7-day placebo phase, resulting in four menstrual cycles per year.[25] Another product provides hormone-containing tablets daily throughout the year.[15] Women taking extended-cycle and continuous-cycle tablets tend to have a decreased amount of bleeding over time, often leading to amenorrhea. Continuous combination regimens provide OCs for 21 days, then very-low-dose estrogen and progestin for an additional 4 to 7 days (during the traditional placebo phase).[26,27]

OCs containing newer progestins (desogestrel, drospirenone, gestodene, and norgestimate) are referred to as third-generation OCs. These progestins are potent progestational agents that have no estrogenic effects and are less androgenic compared with levonorgestrel on a weight basis. Therefore, these agents are thought to have improved side-effect profiles, such as improving mild to moderate acne.[3–5] Drospirenone also has antimineralocorticoid and antialdosterone activities, which may result in less weight gain compared to use of OCs containing levonorgestrel.[3–5] Few clinical trials have compared OCs and sample sizes are small, so the actual relevance of these differences in progestins remains unknown. A review by the Cochrane Library concluded that there was no evidence supporting a causal association between combination OCs or combination skin patches and weight gain.[28] Table 88–4 lists available OC products by brand name and specifies hormonal composition.

Progestin-only "minipills" (28 days of active hormone per cycle) are also available options.[3–5,14] Progestin-only oral contraceptives are less effective than combination OCs and are associated with irregular and unpredictable menstrual bleeding.[3–5] Minipills must be taken every day of the menstrual cycle at approximately the same time to maintain contraceptive efficacy. If a progestin-only oral contraceptive is taken more than 3 hours late, patients should use a backup method of contraception for 48 hours.[4] Minipills may not block ovulation (nearly 40% of women continue to ovulate normally), so the risk of ectopic pregnancy is higher with their use than with other hormonal contraceptives.

Initiating an Oral Contraceptive. 4 Oral contraceptives may be initiated by several different methods, including on the first day of bleeding during the menstrual cycle, on the first Sunday after the menstrual cycle begins or on the fifth day after the menstrual cycle begins. The most popular method is to begin pills on the first Sunday after the menstrual cycle begins, as this may provide for weekends free of menstrual periods.[3,4,29] Women should be instructed to use a second method of contraception for at least 7 days after initiation for maximum effectiveness. It may be preferable to have women use additional contraception for the entire first cycle, due to user failure in the first month. In the "quick start" method for initiating OCs, the patient takes the first tablet on the day of her office visit.[3,4,29] Women should be instructed to use a second method of contraception for at least 7 days and informed that the menstrual period will be delayed until completion of the active tablets in the current OC pack. This method has been shown to be more successful in getting women to start OCs and to continue using OCs through the third cycle of use.

In the postpartum phase, there is concern about use of OCs because of the mother's hypercoagulability and the effects on lactation. The WHO precautions state that, in the first 21 days postpartum (when the risk of thrombosis is higher), estrogen-containing hormonal contraceptives should be avoided if possible (Table 88–3).[13] If contraception is required during this period, progestin-only oral contraceptives, injectable medroxyprogesterone acetate, and IUDs are acceptable choices. Although a review by the Cochrane Library indicated that existing randomized, controlled trials were insufficient to establish an effect of CHC, if any, on milk quality and quantity, the WHO recommends that women who are breastfeeding avoid CHCs in the first 6 weeks postpartum.[13,30] WHO precautions cite concerns about hormonal exposure in the newborn and diminished quality and quantity of breast milk due to early exposure to CHCs. Progestin-only oral contraceptives do not adversely affect milk production, so they can be used after 6 weeks postpartum. Once effective lactation has been established, particularly in women who are not exclusively breastfeeding, estrogen-containing hormonal contraceptives can be safely used.

Choice of Oral Contraceptive. 1 2 Because all combined OCs are similarly effective in preventing pregnancy, the initial choice is based on the hormonal content and dose, preferred formulation, and coexisting medical conditions (Table 88–3).[13] In women without coexisting medical conditions, an OC containing 35 mcg or less of EE and less than 0.5 mg of norethindrone or an equivalent progestin is recommended (Table 88–4).[5] This strategy is based on evidence that complications and side effects from CHC (i.e., VTE, stroke, or MI) result from excessive hormonal content.[3–5,14] Adolescents, underweight women (less than 50 kg [110 lbs]), women older than 35 years, and those who are perimenopausal may have fewer side effects with OCs containing 20 to 25 mcg of EE. With nonadherence to OCs, the risk of pregnancy may be greater in women taking OCs containing less than 35 mcg of EE. Overweight and obese women may have higher contraceptive failure rates with low dose OCs and may benefit from pills containing at least 35 mcg of EE. Women with regular heavy menses initially may benefit from a 50 mcg EE OC because of their higher endometrial activity and women with regular light menses can be started on 20 mcg EE OCs. Women with oily skin, acne, or hirsutism should be given low androgenic OCs.[5]

Conventional regimens (21 days of active pills, 7 days of placebo) provide predictable menses. Because monophasic OCs may be easier to take, easier to identify/manage side effects, and easier to manipulate to alter the timing of the menstrual cycle, they are preferred over multiphasic OCs.[3–5] Extended-cycle OCs either eliminate or reduce the number of menstrual cycles per year, leading to less premenstrual symptoms and dysmenorrhea. Commercially available extended-cycle OCs are available, or monophasic 28 day OCs can be cycled by skipping the 7-day placebo phase. With continued use of extended-cycle OCs for 1 year, no significant changes adverse effects have been noted. However, long-term studies have not been performed to assess the risk of cancer, VTE, or changes

TABLE 88-4 Composition of Commonly Prescribed Oral Contraceptives[a]

Product	Estrogen	Micrograms[b]	Progestin	Milligrams[b]	Spotting and Breakthrough Bleeding

in fertility. Continuous combination regimens provide a shortened pill-free interval, from the traditional 7 days to 2 to 4 days. These regimens may be beneficial for women with symptoms such as dysmenorrhea or menstrual migraines.

Coexisting medical conditions and their impact on CHC use have been previously addressed. Women with migraine headaches, history of VTE, cardiovascular disease, cerebrovascular disease, and SLE with vascular disease are good candidates for progestin-only methods. In addition, women with a history of estrogen dependent cancer, smokers over the age of 35, and those who are postpartum and/or breastfeeding should use progestin-only or nonhormonal methods.[13,17]

Managing Oral Contraceptive Side Effects. 3 Many symptoms occurring with early OC use (e.g., nausea, bloating, breakthrough bleeding) improve spontaneously by the third cycle of use after adjusting to the altered hormone levels.[3–5] Women should be counseled to continue their OC for 2 to 3 months before a change is made to adjust the hormonal content. However, a large majority of women who discontinue OCs do so because of the side effects. Patient education and early reevaluation within 3 to 6 months are necessary to identify and manage adverse effects, in an effort to improve adherence. A list of OC-related side effects and their management is given in Table 88–2.

If the patient has symptoms related to OC use, it is necessary to determine if the symptom indicates the presence or potential development of a serious illness (Table 88–5).[4,5] Patients should be instructed to immediately discontinue CHCs if they experience warning signs, described as ACHES (abdominal pain, chest pain, headaches, eye problems, and severe leg pain).[4]

Managing Oral Contraceptive Drug Interactions. 3 The effectiveness of an OC is sometimes limited by drug interactions that interfere with gastrointestinal absorption, increase intestinal motility by altering gut bacteriologic flora, and alter the metabolism, excretion, or binding of the OC.[4,17,31] The lower the dose of hormone in the OC, the greater the risk that a drug interaction will compromise its efficacy. Women should be instructed to use an additional method of contraception if there is a possibility of a drug interaction altering the efficacy of the OC.[4] Although less well documented, these recommendations generally also apply to patients receiving transdermal and vaginal CHC products.

Of all antibiotics, rifampin is the one with a true documented pharmacokinetic interaction. Pharmacokinetic studies of other antibiotics have not shown any consistent interaction, but case reports of individual patients have shown a reduction in EE levels when OCs are taken with tetracyclines and penicillin derivatives.[31,32] The ACOG states that ampicillin, doxycycline, fluconazole, metronidazole, miconazole, fluoroquinolones, and tetracyclines do not decrease steroid levels in women taking OCs.[17] The Council on Scientific Affairs at the American Medical Association recommends that women taking rifampin should be counseled about the risk of OC failure and advised to use an additional nonhormonal contraceptive agent during the course of rifampin therapy. The council also recommends that women be informed about the small risk of interactions with other antibiotics, and, if desired, appropriate additional nonhormonal contraceptive agents should be considered. In addition, women who develop breakthrough bleeding during concomitant use of antibiotics and OCs (and other CHCs) should be advised to use an alternate method of contraception during the period of concomitant use.[31]

Women receiving certain anticonvulsants for a seizure disorder should be offered another form of contraception such as IUDs, injectable medroxyprogesterone, implants or nonhormonal options. Some anticonvulsants (mainly phenobarbital, carbamazepine, phenytoin) induce the metabolism of estrogen and progestin, inducing breakthrough bleeding and potentially reducing contraceptive efficacy. In addition, some anticonvulsants (e.g., phenytoin) are known teratogens.

Patient Instructions with Oral Contraceptives. 4 Many women who take OCs are not educated properly on the appropriate use of these medications. Women should be given the package insert that accompanies all estrogen products and instructed to read it. The written patient information should be supplemented with verbal information describing the mechanism of the medication, both common and serious side effects and management of these side effects. Although several transient self-limiting side effects often occur, the patient should be aware of the danger signals that require immediate medical attention (Table 88–5). The benefits and risks should be discussed, including the fact that OCs provide no physical barrier to the transmission of STDs, including HIV. Detailed instructions on when to start taking the OC should be provided. Patients should be told the importance of routine daily administration to ensure consistent plasma concentrations and improve adherence and specific instructions should be given regarding what to do if a tablet is missed. The World Health Organization's Selected Practice Recommendations for Contraceptive Use was updated recently with regard to missed oral contraceptives.[33] In addition to when the tablet(s) is missed and how many are missed, the guidelines take into consideration whether the OC contains less than 30 mcg of EE. Limited evidence suggests that the risk of pregnancy is greater when 20 mcg tablets are missed than when 30 to 35 mcg tablets are missed. For instance, if a woman is taking a tablet containing 20 mcg EE and misses one dose or starts a pack 1 day late, she should take a tablet as soon as possible (two tablets on the same day) and then continue taking the rest of the tablets daily. No additional contraceptive protection is necessary. If, however, two or more tablets are missed or the pack is started 2 or more days late, the woman should follow the same instructions, but condoms should be used or she should abstain from sexual intercourse until she has taken active tablets for 7 days in a row. If missed tablets occur in the third week, she should finish the active tablets in the current pack and start a new pack the next day. She should not take the 7 inactive tablets. If the missed doses occur in the first week and unprotected intercourse has occurred, she should consider the use of emergency contraception. Instructions are similar for the 30 to 35 mcg tablets; however, no additional contraceptive protection is necessary unless three or more active tablets are missed or the woman starts a pack 3 or more days late. It should be noted that the

TABLE 88-5 Serious Symptoms That May Be Associated with Combined Hormonal Contraception

Serious Symptoms	Possible Underlying Problem
Blurred vision, diplopia, flashing lights, blindness, papilledema	Stroke, hypertension, temporary vascular problem of many possible sites, retinal artery thrombosis
Numbness, weakness, tingling in extremities, slurred speech	Hemorrhagic or thrombotic stroke
Migraine headaches	Vascular spasm, stroke
Breast mass, pain, or swelling	Breast cancer
Chest pain (radiating to left arm or neck), shortness of breath, coughing up blood	Pulmonary embolism, myocardial infarction
Abdominal pain, hepatic mass or tenderness, jaundice, pruritus	Gallbladder disease, hepatic adenoma, pancreatitis, thrombosis of abdominal artery or vein
Excessive spotting, breakthrough bleeding	Endometrial, cervical, or vaginal cancer
Severe leg pain (calf, thigh), tenderness, swelling, warmth	Deep-vein thrombosis

Data from Hatcher and Nelson,[4] and Dickey.[5]

Society of Obstetricians and Gynecologists of Canada also recently published guidelines in 2008 for missed doses.[34] These guidelines differ slightly and do not account for the estrogen content of the tablet. Instructions also may vary in package inserts, which can make for increased confusion with patients and providers. It may be prudent, when differing instructions exist, to recommend the more conservative of approaches when dealing with individual patient situations.

Discontinuing Oral Contraceptives and Return of Fertility. The ACOG states that there is no evidence that OC use decreases subsequent fertility. The transdermal patch and vaginal ring CHCs also have similar effects on fertility. The average delay in ovulation after discontinuing OCs is 1 to 2 weeks; however, delayed ovulation is more common in women with a history of irregular menses. If amenorrhea does continue beyond 6 months, women should be counseled to see a gynecologist for further fertility workup.[3–5,17] Traditionally, women are counseled to allow two to three normal menstrual periods before becoming pregnant to permit the reestablishment of menses and ovulation. However, in several large cohort and case-control studies, infants conceived in the first month after discontinuation of an OC had no greater chance of miscarriage or being born with a birth defect than those born in the general population.

Transdermal Contraceptives 1 2 A CHC is available as a transdermal patch (Ortho Evra), which includes 0.75 mg of EE and 6 mg of norelgestromin, the active metabolite of norgestimate.[3–5] Comparative trials have shown the transdermal patch to be as effective as combined OCs in patients weighing less than 90 kg (198 lbs). Of the 15 pregnancies reported in the clinical trials, five were among women weighing more than 90 kg (198 lbs); therefore, this product is not recommended as a first-line option for these women.[3,4,35] Some patients experience application-site reactions, but other side effects are similar to those experienced with OCs (e.g., breast discomfort, headache, and nausea).[3] A warning from the manufacturer states that women using the patch are exposed to approximately 60% more estrogen than from a typical OC containing 35 mcg of EE, but the mechanism is unclear. It is clear that there is increased estrogen exposure, but controversy exists correlating the increased exposure to increased risk of VTE, cardiovascular, and cerebrovascular events. Two epidemiologic studies present conflicting results. One trial indicates a higher incidence of VTE with the patch compared with a typical OC, whereas the other trial indicates there is no significant difference.[35–37] Currently, the U.S. Food and Drug Administration (FDA) is monitoring this risk because more consistent data are needed. The patch should be applied to the abdomen, buttocks, upper torso, or upper arm at the beginning of the menstrual cycle and replaced every week for 3 weeks (the fourth week is patch free).[3,4] The patch releases estrogen and progestin for 9 days. If the woman forgets to change her patch or restarts the active patches after the ninth day, a backup method should be used for 7 days. Approximately 5% of patches will need to be replaced because they become partly detached or fall off altogether, so single replacements are available. If the patch is detached for more than 24 hours, a new 4-week cycle should be started and a backup method used for 7 days.[3,4] Users have demonstrated greater adherence with the patch than with an OC, but whether this results in reduced pregnancy rates remains to be seen.[38] The benefits of adherence must be weighed against of the risk of increased estrogen exposure and possibility of VTE.

Vaginal Rings 1 2 The vaginal contraceptive ring contains EE and etonogestrel (NuvaRing).[39] It is a 54-mm flexible ring, 4 mm in thickness.[3] Over a 3-week period, the ring releases approximately 15 mcg/day of EE and 120 mcg/day of etonogestrel. Comparative trials have shown the vaginal ring to be as effective as combined OCs. On the first cycle of use, the ring should be inserted on or before the fifth day of the menstrual cycle, remain in place for 3 weeks, then removed for 1 week to allow for withdrawal bleeding. The new ring should be inserted on the same day of the week as it was during the last cycle, similar to starting a new OC pack on the same day of the week. A second method of contraception should be used if the ring has been expelled accidentally for more than 3 hours; if less than 3 hours, it should be washed and reinserted.[3,39]

3 Side effects, precautions, and contraindications for use of the hormonal ring are similar to those for all CHCs. The most commonly reported reasons for discontinuation of use were device-related issues, such as foreign-body sensation, device expulsion, and vaginal symptoms. Cycle control with the vaginal ring appears to be equal or better than combined OCs, with a low incidence of breakthrough bleeding and spotting after the second cycle of use, presumably due to increased adherence and release of steady levels of estrogen and progestin.[40,41] Patient acceptability of the delivery system has been studied, and the majority of women do not complain of discomfort in general or during intercourse.[3] A potential concern is the possibility of increased VTE since etonogestrel, is a metabolite of desogestrel which may be associated with increased risk. A few cases of VTE have been reported in clinical trials, but currently there are no published data to support this concern.[3]

The ring should be inserted vaginally. In contrast to diaphragms and cervical caps, precise placement is not an issue because the hormones are absorbed anywhere in the vagina. Women should be in a comfortable position, and compress the ring between the thumb and index finger and push it into the vagina. There is no danger of inserting the ring too far because the cervix will prevent it from traveling up the genital tract. Removal of the ring is performed in a similar manner; pulling it out and discarding into the foil patch (the ring should not be flushed down the toilet).[39] Patients should be discouraged from douching, but other vaginal products, including antifungal creams and spermicides, can be used.[3,4,39]

Long-Acting Injectable and Implantable Contraceptives

Steroid hormones provide long-term contraception when injected or implanted into the skin. Progestins are used in existing injectable and implantable contraceptives.[3–5] Sustained progestin exposure blocks the LH surge, thus inhibiting ovulation. Should ovulation occur, progestins reduce ovum motility in the fallopian tubes. Even if fertilization occurs, progestins thin the endometrium, reducing the chance of implantation. Progestins also thicken the cervical mucus, producing a barrier to sperm penetration. These long-acting methods of contraception do not provide any protection from STDs.

1 2 Women who particularly benefit from progestin-only methods are those who are breast-feeding, those who are intolerant to estrogens (i.e., have a history of estrogen-related headache, breast tenderness, or nausea) or those with concomitant medical conditions in which estrogen is not recommended (Table 88–3). Additionally, injectable and implantable contraceptives are beneficial for women with adherence issues. Pregnancy failure rates with long-acting progestin contraceptives are comparable to the rates with female sterilization.[3–5] Reports have stated an increased risk of ectopic pregnancies while using progestin-only methods, but no evidence supports this finding with use of the more recent injectable and implantable products.

Injectable Progestins. 1 2 Medroxyprogesterone acetate is similar in structure to naturally occurring progesterone. DMPA (Depo-Provera) is administered every 3 months either by deep intramuscular injection in the gluteal or deltoid muscle or subcutaneously in the abdomen or thigh within 5 days of onset of menstrual bleeding.[42,43] With perfect use, the efficacy of DMPA is more than 99%; however, with typical use, 3% of women experience unintended pregnancy.[4] Although these injections may inhibit ovulation for up to 14 weeks, the dose should be repeated every 3 months (12 weeks) to ensure continuous contraception. The manufacturer recommends excluding pregnancy in women with a lapse of 13 or

more weeks between injections for the intramuscular formulation or 14 or more weeks between injections for the subcutaneous formulation. Depo-Provera is available as a 150 mg/mL injection vial or prefilled syringe for IM injection and Depo-SubQ Provera 104 is available as a prefilled syringe.[42,43]

Although no adverse effects have been documented in infants exposed to DMPA through breast milk, the manufacturer recommends not initiating DMPA until 6 weeks postpartum in breastfeeding women. Women who are not breastfeeding but require contraception can receive DMPA immediately postpartum.[13,42] Women with sickle cell disease are good candidates for DMPA, as studies have demonstrated a reduction in sickle cell pain crises in women using DMPA.[13] In addition, women with seizure disorders may experience fewer seizures when taking DMPA for contraception.[4] The subcutaneous DMPA formulation is FDA approved for treatment of endometriosis-associated pain.[43] The incidence of *Candida* vulvovaginitis, ectopic pregnancy, and pelvic inflammatory disease, as well as endometrial and ovarian cancer, is decreased in women using DMPA for contraception compared with women using no contraception.[3,42]

Because return of fertility may be delayed after discontinuation of DMPA, it should not be recommended to women desiring pregnancy in the near future. The median time to conception from the first omitted dose is 10 months. Sixty-eight percent of women will be able to conceive within 12 months, 83% within 15 months, and 93% within 18 months of the last injection.[42,43]

3 Menstrual irregularities are the most frequent adverse effects of both formulations of DMPA. In some cases, bleeding is severe enough to cause a significant drop in hemoglobin. Women who cannot tolerate prolonged bleeding may benefit from a short course of estrogen (e.g., 7 days of 2 mg estradiol or 1.25-mg conjugated estrogen given orally).[3,4] The incidence of irregular bleeding decreases from 30% in the first year to 10% thereafter. After 12 months of therapy, 55% of women report amenorrhea, with the incidence increasing to 68% after 2 years.[42,43] However, bleeding patterns beyond 1 year of use have not been established for the subcutaneous formulation.[43,44]

Other adverse effects, including breast tenderness, weight gain, and depression occur less commonly (less than 5%). However, weight gain averages 1 kg (2.2 lbs) annually and may not resolve until 6 to 8 months after the last injection.[42,43]

DMPA has been associated with short-term bone loss in younger women of reproductive age. This potential side effect may be due to lower ovarian estrogen production that occurs when gonadotropin secretion is suppressed.[17,45,46] Longitudinal studies of women over the age of 18 have shown significant declines in hip and/or spinal BMD when used for up to 2 years compared with those who did not use the medication. This effect appears to be partially reversible after discontinuation of treatment, and no studies have found evidence of osteoporosis or fractures in these users. The largest longitudinal study of adult women in the United States found that within 30 months following DMPA discontinuation, BMD of the spine and hip was similar to that of nonusers.[47] There is evidence from cross-sectional studies, however, to suggest that use of DMPA during adolescence before peak bone mass is achieved is detrimental in high-risk patients. Decreases in lumbar spine BMD of 1.5% and 3.1% in DMPA users after 1 and 2 years of use respectively have been demonstrated, compared with a 2.9% and 9.5% increase in controls over the same time periods. Because of these demonstrated effects on BMD, the FDA issued a black box warning for DMPA in 2004.[42,43] It states that DMPA should be continued for more than 2 years only if other contraceptive methods are inadequate. It also states that this loss seems to be greater with increasing duration of use and may not be completely reversible. Ultimately, it is unclear whether use of DMPA during adolescence or early adulthood will increase the risk of fracture later in life or prevent them from achieving normal peak bone mass. What is clear is that clinicians should counsel patients on the benefits versus the risks of the medication and to make recommendations based upon available evidence. Patients should be encouraged to have an adequate daily intake of calcium and vitamin D and to exercise daily. Although controversial, some clinicians are recommending evaluations of BMD for those women on DMPA for greater than 2 years. However, ACOG does not currently recommend monitoring BMD solely in response to DMPA use.[45] This recommendation is based upon the fact that any observed short-term loss in BMD associated with DMPA use may be recovered and is unlikely to place a woman at risk of fracture during use or in later years.

Subdermal Progestin Implants. 1 2 Implanon is a single 4-cm-long implant, containing 68 mg of etonogestrel, that is placed under the skin of the upper arm using a preloaded inserter.[48] Implanon releases etonogestrel at a rate of 60 mcg daily for the first month, then decreases to an average of 30 mcg daily at the end of the 3 years of recommended use. Etonogestrel suppresses ovulation in 97% of cycles. When ovulation is not suppressed, etonogestrel still is effective as the progestin thickens the cervical mucus and produces an atrophic endometrium. With perfect use, efficacy approaches 100% but may be reduced in women weighing more than 130% of their ideal body weight. Because only one rod is used, the difficulties experienced with insertion and removal hopefully will be avoided.

4 The etonogestrel implant should be inserted between days 1 and 5 of the menstrual cycle in women who have not previously used hormonal contraception.[48] Women currently taking OCs can have the implant inserted within 7 days after taking the last active OC tablet. Women currently taking progestin-only oral contraceptives should have the implant inserted without skipping any days, on the same day that the progestin-only IUD is removed, or on the day that the DMPA injection is due. After removal, fertility returns within 30 days.

3 The major adverse effect associated with Implanon is irregular menstrual bleeding, which led to discontinuation of the implant in 11% of patients in clinical trials.[48] Like the bleeding pattern seen with other progestins, some women (22%) became amenorrheic with continued use, but many continued to have prolonged bleeding and spotting (18%) and frequent bleeding (7%). Other adverse effects include headache, vaginitis, weight gain, acne, and breast and abdominal pain. The role of the progestin implant's influence on BMD has become an area of controversy since the FDA required an inclusion of a black box warning for DMPA. In theory, the etonogestrel implant system should not decrease BMD as much as DMPA because estrogen concentrations are not as consistently suppressed. Clinical trials have demonstrated no significant relationship between use of the hormonal implant and changes in BMD. In addition, there are no long-term data and no data demonstrating a correlation between the implant and fracture risk or an increase in osteoporosis.[49]

Implanon is a unique implantable contraceptive agent that provides enhanced adherence and prolonged efficacy. Therefore, it may be a good choice for women with a history of non-adherence, those who do not plan to have children for at least 3 years or those who have estrogen-related adverse effects or contraindications. Because fertility returns quickly after removal and Implanon does not affect bone health, it may be preferred over DMPA. Women should be counseled about the risk of irregular bleeding patterns so that patients will not request early removal of Implanon.

Intrauterine Devices

1 2 The low-grade intrauterine inflammation and increased prostaglandin formation caused by IUDs and endometrial suppression caused specifically by the progestin-releasing IUD appear to be

primarily spermicidal, although interference with implantation is a backup mechanism.[3,4,50,51] Efficacy rates with IUDs are greater than 99% with both perfect and typical use.[4] Although they are a very effective form of contraception and are increasing in popularity, the IUD still has several contraindications. Patients who should be excluded from use of IUDs include: current pregnancy, pelvic inflammatory disease (current or within past 3 months), STD (current), puerperal or postabortion sepsis, purulent cervicitis, undiagnosed abnormal vaginal bleeding, malignancy of genital tract, uterine anomalies or fibroids distorting uterine cavity, allergy to IUD component, Wilson's disease (for copper IUD). The risk of pelvic inflammatory disease among IUD users ranges from 1% to 2.5%. Because the increased risk of infection appears to be related to introduction of bacteria into the genital tract during IUD insertion, the risk is highest during the first 20 days after the procedure.[51,52] Two IUDs currently are marketed in the United States; all are T-shaped and are medicated, one with copper (ParaGard) and one with levonorgestrel (Mirena).[3,4]

3 ParaGard provides better contraceptive effectiveness than previous copper devices and can be left in place for 10 years.[3,4] A disadvantage of ParaGard is increased menstrual blood flow and dysmenorrhea; average monthly blood loss among users increased by 35% in clinical trials. Mirena was released in the United States in 2001 and is becoming more widely used. It releases 20 mcg of levonorgestrel daily, but release decreases to 10 mcg daily over the 5 years of use.[3,4,50,51] Systemically absorbed levonorgestrel is minimal and considerably less than with OCs. The levonorgestrel IUD produces its effects locally via suppression of the endometrium, causing a reduction in menstrual blood loss. In contrast to the copper IUD, menstrual flow in users of the levonorgestrel IUD is decreased, and development of amenorrhea has been observed in 20% of users in the first year and 60% in the fifth year. A disadvantage of the levonorgestrel IUD is increased spotting in the first 6 months of use; women should be counseled that the spotting will decline gradually over time.[3,4,50,51]

IUDs should be considered because adherence is not an issue once inserted and result in immediate return of fertility once removed. The levonorgestrel IUD has many noncontraceptive benefits, specifically, it is a good choice for women with menorrhagia or dysmenorrhea because it reduces and may eliminate menstrual blood loss. IUDs, in general, are an alternative for women who cannot tolerate or have contraindications to estrogen-containing contraceptive agents. Recently, use in the adolescent and nulliparous population has been recommended in a select group of appropriate candidates due to the high contraceptive efficacy rate. It is important to adhere to the IUD contraindications and provide appropriate counseling to this population. Data to support wide use of this practice in this population are limited.[53]

CLINICAL CONTROVERSY

Use of IUDs is low in adolescents. Specifically in this group, patients and clinicians are concerned about the risk of pelvic inflammatory disease, infertility, and insertion complications. It is important to note there is limited evidence in adolescent and nulliparous women. However, it appears use in this population may be safe when used in appropriate candidates. Adolescent women need to be appropriately screened and counseled on STDs. In addition, these adolescent and nulliparous women have the highest risk of IUD expulsion and pain on insertion. Risks and benefits must be discussed with all patients prior to IUD insertion. The ACOG committee on adolescent healthcare endorses use of IUDs in adolescents who are appropriate candidates due to the high efficacy rates and the need to reduce pregnancy rates in adolescents.

Emergency Contraception

5 EC is used to prevent unwanted pregnancy after unprotected sexual intercourse, including condom breakage, diaphragm dislodging, or sexual assault. Higher doses of combined estrogen and progestin or progestin-only containing products can be used.[3–5] Insertion of copper IUD is an option, although it is not an FDA approved or a widely used method of EC. Currently, a progestin-only formulation containing levonorgestrel (currently marketed as Plan B, Plan B One-Step, Next Choice) is approved specifically for EC in the United States.[3–5,54] Exact mechanisms of action of oral EC are being studied and vary according to the product used and the time a woman takes it in relation to her menstrual cycle.

Recent studies support that the primary mechanism of action of Plan B is inhibiting or delaying ovulation. Additional evidence suggests it may impair sperm transport and corpus luteum function, therefore inhibiting fertilization. The most recent data does not support that it may prevent the fertilized egg from implanting into the endometrium. Further research is ongoing in this area.[3,4,54–56] Pregnancy occurs when the fertilized egg is implanted into the endometrial lining. After intercourse, implantation of the fertilized egg typically takes approximately 5 days. Oral EC will not disrupt the fertilized egg after implantation has occurred.[3,4,54] The levonorgestrel-containing EC formulation is the regimen of choice due to availability, improved tolerability, and potentially increased efficacy rates. Plan B and Next Choice contain two tablets, each containing 0.75 mg of levonorgestrel. The first dose is taken within 72 hours of unprotected intercourse (although the sooner, the more effective); the second dose is taken 12 hours later.[3–5,54] One study found that 1.5 mg of levonorgestrel (two tablets of Plan B) taken as a single dose was as effective as taking the doses 12 hours apart and did not cause an increased incidence of adverse effects.[54,57] Due to this evidence, a new formulation (Plan B One-Step) containing 1 tablet of 1.5 mg of levonorgestrel taken within 72 hours of unprotected intercourse is currently being marketed and the older Plan B may be phased out.[58] Plan B was approved by the FDA in 2006 for OTC sales, as of 2009 it may be sold without a prescription to patients 17 years of age and older. It is sold only in pharmacies and must be stocked behind the counter. Patients must provide proof of age prior to purchasing the product. The manufacturer is continuing its efforts in gaining OTC status for increased provision to minors.[59]

5 Despite the availability of progestin-only EC formulations, use of regular combined contraceptives for EC (i.e., Yuzpe method) still is permissible, although some studies suggest that they may not be as effective and may be associated with more adverse effects.[3,4,54] Specifically, the FDA has declared the following regimens containing the progestins norgestrel and levonorgestrel safe and effective methods of EC: Ovral and Ogestrel (two tablets per dose); Nordette, Levlen, Levora, Lo/Ovral, Low-Ogestrel, Cryselle, Jolessa, Enpresse, Portia, Seasonale, Seasonique, Triphasil, TriLevlen, or Trivora (four tablets per dose); and Alesse, Aviane, Lessina, Levlite, or Lutera (five tablets per dose).[3–5,43] Additionally, regular progestin-only oral contraceptives can be used as EC, but many tablets must be taken (i.e., Ovrette, 20 tablets per dose).[3,4,54] Patients should be counseled to take the appropriate number of tablets as soon as possible after unprotected sexual intercourse and to repeat the dose in 12 hours. Taking all the tablets at once as a single dose is not recommended when using combination oral contraceptives.

The efficacy of all EC regimens is improved when taken as soon as possible after unprotected intercourse (within the first 24 hours). EC is still effective when taken within 72 hours but begins to decline once that timeframe has elapsed.[3,4,54] However, one study suggests that EC may still be effective when used up to 120 hours after intercourse and should be considered in some women when use is delayed.[54,60] Determining the exact effectiveness rate is difficult;

however, the range has been reported to be between 59% and 94%. A meta-analysis of the literature has reported that EC may prevent an average of 75% of expected pregnancies when taken appropriately. It is recommended that women have an advanced prescription on hand or access to an OTC formulation to maximize the effectiveness of EC.[3,4,54]

Common adverse effects include nausea, vomiting, and irregular bleeding. Nausea and vomiting occur significantly less when progestin-only EC is administered. If the Yuzpe method is prescribed, antiemetics given 1 hour before the dose is taken may be warranted to prevent the increased amount of estrogen-induced gastrointestinal adverse effects. Many women will experience irregular bleeding regardless of which EC method is used, with the menstrual period usually occurring 1 week before or after the expected time. No current data regarding the safety of repeated use EC are available, but current consensus suggests the risks are low, and women can receive multiple regimens if warranted. Pharmacists and other healthcare providers have a key role in providing patient counseling regarding EC. Appropriate counseling should be provided regarding timing of the dose, common adverse effects, and use of a regular contraceptive method (backup barrier methods should be used after EC for at least 7 days).[54]

CLINICAL CONTROVERSY

Pharmacists who refuse to fill valid prescriptions for emergency contraception have been highly publicized in the media. Position statements published by the American Pharmaceutical Association and American College of Clinical Pharmacy support pharmacists' rights to decline filling a valid prescription if doing so conflicts with moral, ethical, or religious beliefs. However, it is the pharmacists' professional responsibility to refer the patient to another pharmacist who will fill the prescription in a timely, confidential, and nonjudgmental manner so that no harm is caused to the patient.

PHARMACOECONOMIC CONSIDERATIONS

About one third of all pregnancies in the United States are unintended.[1] Not all unintended pregnancies are unwanted; many are just "mistimed." The United States has a higher rate of induced abortions than most other industrialized western nations. Whatever method is used, preventing unintended pregnancy is highly cost-effective. With regard to the acquisition cost of reversible contraception, the most cost-effective barrier method is the male condom. However, reliable pharmacologic methods can also be cost-effective. Injectable, implantable, and IUD options may carry a higher initial cost but would be comparable or even less costly in the long run. OCs, the contraceptive patch, and the vaginal ring are actually the most expensive forms of reversible contraception yet are the most commonly utilized in this country. Overall, with regard to direct medical costs (e.g., method use, adverse effects, and unintended pregnancies) over 5 years, IUDs are the most cost-effective method of contraception, along with sterilization. All contraceptive options (barrier and pharmacologic) are more cost-effective than no method at all.[61]

EVALUATION OF THERAPEUTIC OUTCOMES

4 Patients should receive both verbal and written instructions on the chosen method of contraception. Follow-up appointments can increase adherence and provide opportunities to address other health maintenance issues (e.g., self-breast examination, Pap smears, human papillomavirus vaccines, STD risk).[4]

Annual blood pressure monitoring is recommended for all users of CHC. When a patient with a history of glucose intolerance or diabetes mellitus begins or discontinues the use of CHC, glucose levels must be monitored closely for deterioration of the condition. Contraceptive users should also receive annual (more frequent if they are at risk for STDs) cytologic screening as well as annual examination for clinical problems related to CHC (e.g., breakthrough bleeding, weight gain, acne).

Women using Implanon should be monitored annually for menstrual cycle disturbances, weight gain, local inflammation, or infection at the implant site, acne, breast tenderness, headaches, and hair loss. Women using DMPA should be asked at 3-month follow-up visits about weight gain, menstrual cycle disturbances, and STD risks. Patients taking DMPA should be weighed, undergo blood pressure checks, and receive annual examinations as indicated based upon the age of the patient. Women using IUDs should be asked at 1- to 3-month follow-up visits about IUD placement (checking for IUD strings to assure the IUD is still in the proper position), changes in menstrual bleeding patterns, and symptoms and protection against STDs. Providers should check for proper IUD positioning and symptoms of upper genital tract infection.

Choosing a contraceptive method most suited to the patient's needs will reduce the chance of unintended pregnancy. A medical and sexual history and a thorough physical examination are essential when evaluating the various methods available. Understanding the risks and precautions associated with the methods available is essential for both patients and clinicians. Counseling about OTC availability of EC or advanced provision of EC prescription is warranted for all women of child-bearing age. Finally, providers should counsel women about healthy sexual practices and encourage use of male condoms in addition to other barrier or pharmacologic contraceptives when necessary to prevent STDs.

ABBREVIATIONS

ACOG: American College of Obstetrics and Gynecology
BMD: bone mineral density
BMI: body mass index
CDC: Centers for Disease Control and Prevention
CHC: combined hormonal contraception

CHAPTER 89

Menstruation-Related Disorders

ELENA M. UMLAND, LARA CARSON WEINSTEIN, AND EDWARD M. BUCHANAN

KEY CONCEPTS

1. Unrecognized pregnancy is the most common cause of amenorrhea. A urine pregnancy test should be one of the first steps in evaluating this disorder.
2. For hypoestrogenic conditions associated with primary and secondary amenorrhea, estrogen (with a progestin) is provided.
3. Causes of menorrhagia are either systemic disorders or specific uterine abnormalities.
4. Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis for any woman presenting with heavy menses.
5. The reduction in menorrhagia-related blood loss with use of nonsteroidal antiinflammatory drugs and oral contraceptives is directly proportional to the amount of pretreatment blood loss.
6. Intrauterine devices (IUDs) are considered therapeutic options in a variety of menstruation-related disorders. Guidelines from the American College of Obstetricians and Gynecologists indicate that both nulliparous and multiparous women at low risk of sexually transmitted diseases are good candidates for IUD use.
7. Anovulatory bleeding is the standard terminology used to describe bleeding from the uterine endometrium as a result of a dysfunctioning menstrual system, specifically excluding an anatomic lesion of the uterus.
8. Polycystic ovarian syndrome can present as a variety of menstruation disorders, including amenorrhea, menorrhagia, and anovulatory bleeding. Although its definition continues to evolve, it is generally considered a disorder of androgen excess that often includes polycystic ovarian morphology and ovulatory dysfunction.
9. Metformin and thiazolidinedione use for anovulatory bleeding associated with PCOS is beneficial not only for anovulatory bleeding and fertility but also for improving glucose tolerance and other metabolic parameters that contribute to cardiovascular risk.
10. The selective serotonin reuptake inhibitors are first-line pharmacologic treatment options for premenstrual dysphoric disorder.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Problems related to the menstrual cycle are exceedingly common in women of reproductive age. This chapter discusses the most frequently encountered menstruation-related difficulties: amenorrhea, menorrhagia, anovulatory bleeding, dysmenorrhea, premenstrual syndrome (PMS), and premenstrual dysphoric disorder (PMDD). The need for effective treatments of these disorders stems from their impact on any or all of the following: a reduced quality of life, negative effects on reproductive health, and potential for long-term detrimental health effects, such as osteoporosis with amenorrhea and cardiovascular disease with polycystic ovary syndrome (PCOS).

AMENORRHEA

Amenorrhea is described as either primary or secondary in nature. Primary amenorrhea is the absence of menses by age 16 years in the presence of normal secondary sexual development or the absence of menses by age 14 in the absence of normal secondary sexual development. Secondary amenorrhea is the absence of menses for three cycles or for 6 months in a previously menstruating woman. There is a significant amount of overlap between the two. The initial evaluation of amenorrhea often is the same, regardless of age of onset, except in unusual clinical situations.[1]

EPIDEMIOLOGY

Primary amenorrhea occurs in less than 0.1% of the general population. Secondary amenorrhea, in comparison, has an incidence of 0.7% to 5% in the general population and occurs more frequently in women younger than 25 years with a history of menstrual irregularities and in those involved in competitive athletics.[2]

ETIOLOGY

1 Unrecognized pregnancy is the most common cause of amenorrhea. A urine pregnancy test should be one of the first steps in evaluating this disorder. In organizing an approach to diagnosis and treatment, it is helpful to consider the organs involved in the menstrual cycle, which include the uterus, ovaries, anterior pituitary, and hypothalamus.

After excluding pregnancy, the most common causes of secondary amenorrhea are hypothalamic suppression, chronic anovulation, hyperprolactinemia, ovarian failure, and uterine disorders.[3]

PATHOPHYSIOLOGY

Each organ in the hypothalamic–pituitary–ovarian–uterine axis is of importance in determining amenorrhea's etiology and pathophysiology. Beginning with the uterus/outflow tract and progressing caudally will result in a comprehensive differential diagnosis.

TABLE 89-1 Pathophysiology of Selected Menstrual Bleeding Disorders

Organ System	Condition	Pathophysiology/Laboratory Findings
Amenorrhea		
Uterus	Asherman syndrome	Postcurettage/postsurgical uterine adhesions
	Congenital uterine abnormalities	Abnormal uterine development
Ovaries	Turner syndrome	Lack of ovarian follicles
	Gonadal dysgenesis	Other genetic abnormalities
	Premature ovarian failure	Early loss of follicles
	Chemotherapy/radiation	Gonadal toxins
Anterior pituitary	Pituitary prolactin-secreting adenoma	↑ Prolactin suppresses HPO axis
	Hypothyroidism	TRH causes ↑ prolactin, other abnormalities
	Medication (antipsychotics, verapamil)	↑ Prolactin suppresses HPO axis
Hypothalamus	"Functional" hypothalamic amenorrhea	↓ Pulsatile GnRH secretion in the absence of other abnormalities
	Eating disorder	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to weight loss
	Exercise	↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to low body fat
	Anovulation/PCOS	Asynchronous gonadotropin and estrogen production, abnormal endometrial growth
Anovulatory bleeding		
Physiologic causes	Adolescence	Immaturity of the HPO axis; no LH surge
	Perimenopause	Declining ovarian function
Pathologic causes	Hyperandrogenic anovulation (PCOS)	Hyperandrogenism: high testosterone, high LH, hyperinsulinemia, and insulin resistance
	Hypothalamic dysfunction (physical or emotional stress, exercise, weight loss)	Suppression of pulsatile GnRH secretion and estrogen deficiency: low LH, low FSH
	Hyperprolactinemia (pituitary gland tumor, psychiatric medications)	High prolactin
	Hypothyroidism	High TSH
	Premature ovarian failure	High FSH
Menorrhagia		
Hematologic	von Willebrand's disease	Factor VII defect causing impaired platelet adhesion and increased bleeding time
	Idiopathic thrombocytopenic purpura	Decrease in circulating platelets, can be acute or chronic
Hepatic	Cirrhosis	Decreased estrogen metabolism, underlying coagulopathy
Endocrine	Hypothyroidism	Alterations in HPO axis
Uterine	Fibroids	Alteration of endometrium, changes in uterine contractility
	Adenomyosis	Alteration of endometrium, changes in uterine contractility
	Endometrial polyps	Alteration of endometrium
	Gynecologic cancers	Various dysplastic alterations of endometrium, uterus, cervix

FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPO, hypothalamic–pituitary–ovarian; LH, luteinizing hormone; PCOS, polycystic ovary disease; TSH, thyroid stimulating hormone; TRH, thyrotropin-releasing hormone.

Data from references 1–6.

Table 89–1 lists the pathophysiology of amenorrhea relative to the organ system(s) involved and the specific condition(s) that results in amenorrhea.

Uterus/Outflow Tract

For menstruation to occur, a uterus, functional endometrium, and patent vagina must be present. Several anatomic abnormalities may cause amenorrhea. If primary amenorrhea is the presenting symptom, a congenital anomaly such as imperforate hymen or uterine agenesis may be present and often discovered by physical examination. An acquired condition of the genital tract, such as Asherman syndrome or cervical stenosis, is more likely in secondary amenorrhea.

Ovaries

Normal ovarian function is critical for menstruation to occur. The ovaries must respond appropriately to follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by secreting estrogen and progesterone in proper sequence to influence endometrial growth and shedding (Fig. 89–1).

Premature ovarian failure occurs when no viable follicles remain in the ovaries. This is because estrogen production is insufficient to stimulate endometrial growth in the absence of follicles. In a woman younger than 30 years, amenorrhea due to premature ovarian failure may be the result of genetic anomalies.[1]

The ovaries may play a role in amenorrhea through anovulation. Ovulation is required for the follicle (an estrogen-secreting body) to become a corpus luteum (a progesterone-secreting body). Without ovulation, the proper sequence of estrogen production, progesterone production, and estrogen/progesterone withdrawal will not occur. This can result in amenorrhea. Anovulation can occur secondary to thyroid disease, androgen excess (PCOS), or chronic illness.

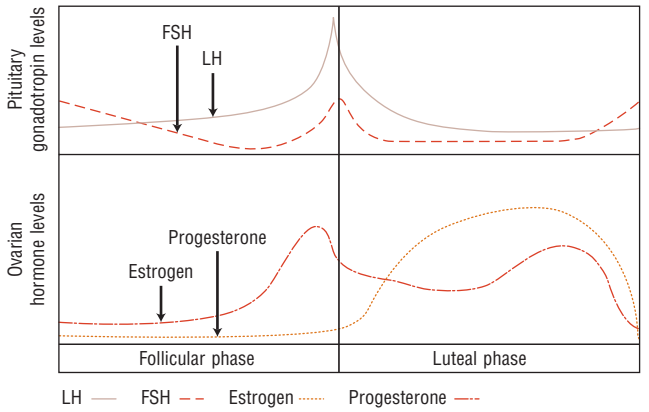

FIGURE 89-1. Summary of the normal menstrual cycle. (FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.)

Pituitary Gland

The anterior pituitary gland secretes FSH and LH in sequential fashion in response to hypothalamic stimulation and a complex ovarian feedback mechanism. Normal secretion of FSH and LH is altered by several endocrinologic and iatrogenic conditions, including thyroid disease, hyperprolactinemia, and dopaminergic drug administration.

Hypothalamus

The hypothalamus secretes cyclic gonadotropin-releasing hormone (GnRH), which causes the pituitary to produce FSH and LH. Disrupting this cyclic excretion will interrupt the hormonal cascade that results in normal menstruation. Anorexia nervosa, bulimia, intense exercise, and stress may cause hypothalamic amenorrhea.

CLINICAL PRESENTATION OF AMENORRHEA

General

- Although patients may be concerned about cessation of menses and implications for fertility, patients are generally not in acute distress.

Symptoms

- Patient will note cessation of menses.
- Patients may complain of infertility, vaginal dryness, or decreased libido.

Signs

- Cessation of menses for more than 6 months in women with established menstruation, absence of menses by age 16 years in the presence of normal secondary sexual development, or absence of menses by age 14 years in the absence of normal secondary sexual development
- Recent significant weight loss or weight gain
- Presence of acne, hirsutism, hair loss, or acanthosis nigrans may suggest androgen excess

Laboratory Tests

- Pregnancy test
- Thyroid-stimulating hormone
- Prolactin
- If PCOS is suspected, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, fasting lipid panel
- If suspect premature ovarian failure, consider FSH, LH

Other Diagnostic Tests

- Progesterone challenge
- Pelvic ultrasound to evaluate for polycystic ovaries

TREATMENT

The treatment options for amenorrhea are as varied as its causes.

Desired Outcome

Therapeutic modalities for amenorrhea should ensure the occurrence of normal puberty and restore the menstrual cycle. Treatment goals include bone density preservation, bone loss prevention, and ovulation restoration, improving fertility as desired. Amenorrhea from hypoestrogenism may affect quality of life via hot flash induction (premature ovarian failure), dyspareunia, and, in prepubertal females, lack of secondary sexual characteristics and absence of menarche. Treatment is targeted at reversing these effects.

General Approach to Treatment

The overall success of any intervention to treat amenorrhea is dependent on proper identification of the disorder's underlying cause(s). Once the cause is identified, the appropriate intervention(s) can be made. For patients experiencing amenorrhea secondary to hypoestrogenic states, a diet rich in calcium and vitamin D is essential to avoid negative impact on bone health.

Nonpharmacologic Therapy

Nonpharmacologic therapy for amenorrhea varies depending on the underlying cause. Amenorrhea secondary to anorexia may respond to weight gain. In young women for whom excessive exercise is an underlying cause, reduction of exercise quantity and intensity are important.

Pharmacologic Therapy

❷ For hypoestrogenic conditions associated with primary or secondary amenorrhea, estrogen (with a progestin) is provided. It can be administered as an oral contraceptive (OC), conjugated equine estrogen, or estradiol patch. Estrogen therapy in this patient population reduces osteoporosis risk[7] and improves quality of life. Table 89–2 lists therapeutic agents for amenorrhea treatment, including recommended doses. Figure 89–2 illustrates a treatment algorithm for management of amenorrhea.

When hyperprolactinemia is the cause of amenorrhea, dopamine agonists, including bromocriptine and cabergoline aid in reducing prolactin concentrations and the resumption of menses. Bromocriptine requires multiple doses per day; cabergoline is dosed twice weekly. When compared with cabergoline, bromocriptine is less effective in normalizing prolactin levels and has a higher incidence of adverse events leading to treatment discontinuation.[10]

Amenorrhea related to PCOS-induced anovulation may respond to agents that reduce insulin resistance. Metformin and the thiazolidinediones for this purpose are discussed in the anovulatory bleeding section.

Progestins induce withdrawal bleeding in women with secondary amenorrhea. Several factors predict progesterone's efficacy for this purpose.[9] These factors include estrogen concentrations greater than or equal to 35 pg/mL (128 pmol/L) and endometrial thickness (greater initial thickness resulting in more withdrawal bleeding).

Progestin efficacy for secondary amenorrhea varies by formulation used. Progesterone in oil administered intramuscularly results in withdrawal bleeding in 70% of treated patients, whereas oral medroxyprogesterone acetate (MPA) induces withdrawal bleeding in 95% of treated patients.[9] Table 89–2 identifies the types and doses of progestins used for secondary amenorrhea treatment. Figure 89–2 illustrates when to consider progestin use for amenorrhea treatment.

Special Populations Amenorrhea in the adolescent population is of concern because this is the developmental time when peak bone mass is achieved. The cause of amenorrhea, whether primary or secondary, must be promptly identified in this population, as amenorrhea and its related hypoestrogenism negatively affect bone development. In addition to treating or eliminating amenorrhea's underlying cause, ensuring that the patient is receiving adequate amounts of calcium and vitamin D is imperative. Estrogen replacement, typically via an OC, is important.

Drug Class Information Table 89–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents used for amenorrhea management.

TABLE 89-2 Therapeutic Agents for Selected Menstrual Disorders

Specific Menstrual Disorder(s)	Agent(s)	Dose Recommended
Amenorrhea (primary or secondary)	CEE	0.625–1.25 mg by mouth daily on days 1–25 of the cycle[8]
	Ethinyl estradiol patch	50 mcg/24 hours[9]
	Combination OC	30–40 mcg formulations[7]
Amenorrhea (secondary)	Oral MPA	5–10 mg by mouth on days 14–25 of the cycle[8]
	Norethindrone	5 mg by mouth daily for 7–10 days[8]
	Micronized progesterone	400 mg by mouth daily for 7–10 days[8]
Amenorrhea related to hyperprolactinemia	Bromocriptine[3,10]	2.5 mg by mouth 2–3 times daily
	Cabergoline[3,10]	0.25 mg by mouth 2 times weekly (maximum 1 mg by mouth 2 times weekly)
Anovulatory bleeding	Combination OC	≤35 mcg ethinyl estradiol
Dysmenorrhea	Combination OC	Less than 35 mcg formulations + norgestrel or levonorgestrel[12]; use of extended-cycle formulations is beneficial for this indication
	Depo MPA[12]	150 mg intramuscularly every 12 weeks
	Levonorgestrel IUD[12,13,15]	20 mcg released daily
	NSAIDs (any are acceptable); the most commonly studied/cited are included in this table	Diclofenac 50 mg by mouth 3 times daily; ibuprofen 800 mg by mouth 3 times daily; mefenamic acid 500 mg by mouth as a loading dose, then 250 mg by mouth up to 4 times daily as needed[14]
		Naproxen 550-mg loading dose by mouth started 1–2 days prior to menses followed by 275 mg by mouth every 6–12 hours as needed[12]
	Celecoxib[12,13,16]	400 mg by mouth followed by 200 mg by mouth every 12 hours as needed during menses
Menorrhagia	Combination OC[18]	Optimal dose unknown
	Levonorgestrel IUD[17,18,19]	20 mcg released daily
	Oral MPA	5–10 mg by mouth on days 5–26 of the cycle or during the luteal phase[15,17]
	NSAIDs [17]	Doses as recommended for dysmenorrhea may be used; therapy should be initiated with the onset of menses[15]
	Tranexamic acid[17,20]	1,300 mg by mouth every 8 hours once heavy bleeding begins; dose for 4–7 days as needed per cycle.
PCOS-related amenorrhea and/or anovulatory bleeding	Depo MPA	150 mg intramuscularly every 12 weeks
	Combination OC[21,22]	≤30 mcg ethinyl estradiol with either desogestrel, norgestimate, or drospirenone
	Oral MPA	10 mg by mouth for 10 days[5]
	Metformin[5,22]	1,500–2,000 mg by mouth daily[22]
	Thiazolidinediones (pioglitazone, rosiglitazone)[5,22]	Pioglitazone 15–45 mg by mouth daily; rosiglitazone 4–8 mg by mouth daily
PMDD	Clomipramine[23]	25–75 mg by mouth daily taken either continuously or only during the luteal phase
	Drospirenone	3 mg (+ ≤30 mcg ethinyl estradiol) by mouth on days 1–21 of the menstrual cycle[24]
	Leuprolide	3.75 mg intramuscularly[23]
	SSRIs[25]	Citalopram 10–30 mg; escitalopram 10–20 mg[26]; fluoxetine 10–20 mg; fluvoxamine 50 mg; paroxetine 10–30 mg; sertraline 25–150 mg; all agents are given by mouth daily and can be dosed either continuously or during the luteal phase only[23]

CEE, conjugated equine estrogen; IUD, intrauterine device; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive; PCOS, polycystic ovary syndrome; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitor.

Data from references 3, 5, 7–10, 12–17, 21–26.

PHARMACOECONOMIC CONSIDERATIONS

The largest price gap among agents used in amenorrhea management occurs when comparing the dopamine agonists bromocriptine and cabergoline in treating hyperprolactinemia. Cabergoline is slightly more effective, with fewer side effects and less frequent dosing, but its monthly cost is significantly greater than bromocriptine. Given this, it is reasonable to reserve its use for patients who are not successfully treated with bromocriptine or for whom bromocriptine's side effects are responsible for drug discontinuation.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 89–4 lists the expected outcomes and specific monitoring parameters for treatment modalities used in amenorrhea management.

MENORRHAGIA

Menorrhagia is traditionally defined by menstrual blood loss greater than 80 mL per cycle. This definition has been questioned because of several factors, including difficulty quantifying menstrual loss in clinical practice. Additionally, many women with "heavy menses" but blood loss less than 80 mL merit treatment consideration because of flow containment issues, unpredictably heavy flow days, or other associated symptoms.[20]

EPIDEMIOLOGY

Menorrhagia rates in healthy women range from 9% to 14%.[4]

ETIOLOGY

❸ Causes of menorrhagia are either systemic disorders or specific uterine abnormalities. ❹ Pregnancy, including intrauterine pregnancy, ectopic pregnancy, and miscarriage, must be at the top of the differential diagnosis for any woman presenting with heavy menses. In several studies of adolescents with acute menorrhagia, underlying bleeding disorders accounted for 3% to 13% of emergency room presentations. For example, von Willebrand's disease has an incidence of 1% in the general population;[29] its prevalence in women with menorrhagia may be as high as 20%.[30] Furthermore, 74% to 92% of women with von Willebrand's disease have menorrhagia.[6] Menorrhagia initially may present as heavy menses in the adolescent.[29] Hypothyroidism also may be

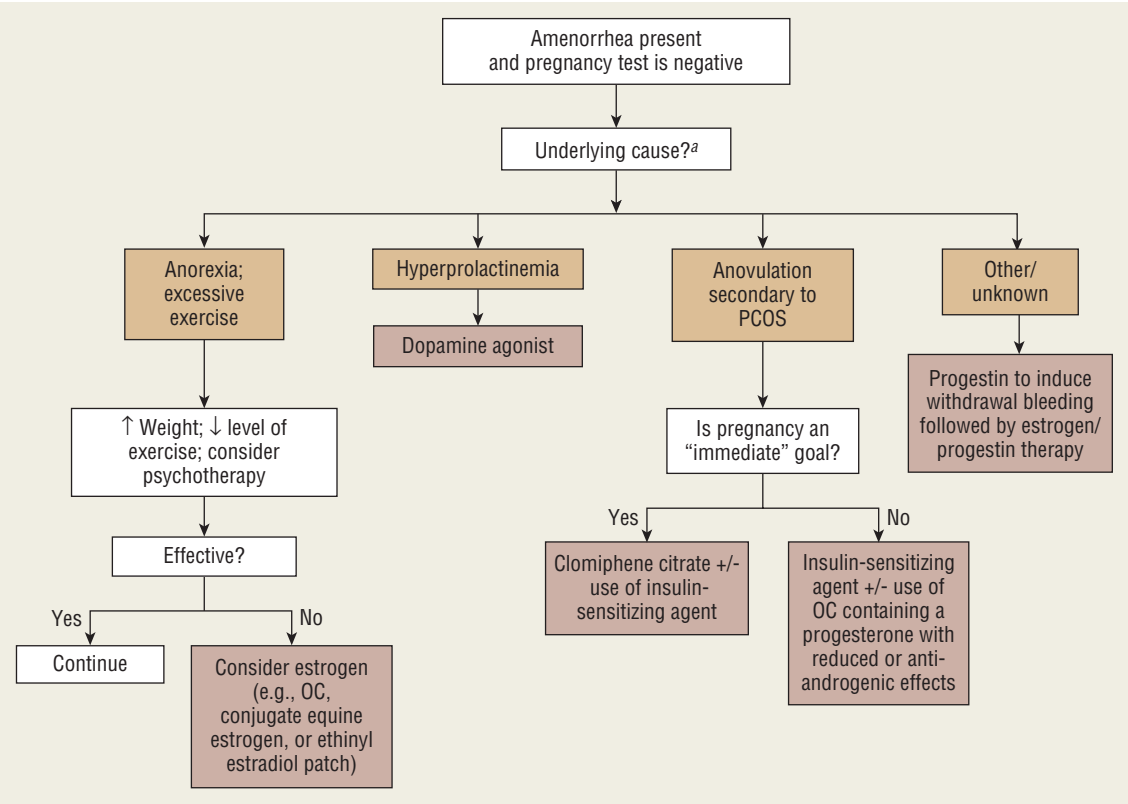

FIGURE 89-2. Treatment algorithm for amenorrhea. [a]Regardless of cause, adequate calcium and vitamin D intake must be ensured. (OC, oral contraceptive; PCOS, polycystic ovary syndrome.)

associated with heavy menses. Specific uterine causes of menorrhagia are more common in older childbearing women and include fibroids, adenomyosis, endometrial polyps, and gynecologic malignancies.

PATHOPHYSIOLOGY

Table 89–1 lists the pathophysiology of menorrhagia relative to the organ system(s) involved and the specific conditions that result in menorrhagia.

CLINICAL PRESENTATION OF MENORRHAGIA

General

- Patient may or may not be in acute distress.

Symptoms

- Patients may complain of heavy/prolonged menstrual flow. They also may have signs of fatigue and lightheadedness in cases of severe blood loss. These symptoms may or may not occur with dysmenorrhea.

Signs

- Orthostasis, tachycardia, and pallor may be noted, especially in cases of significant acute blood loss.

Laboratory Tests

- Complete blood count and ferritin levels; hemoglobin and hematocrit results may be low.
- If the history dictates, testing may be performed to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests

- Pelvic ultrasound
- Pelvic magnetic resonance imaging
- Papanicolaou (Pap) smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram

TREATMENT

Initial treatment choice for menorrhagia is influenced by whether or not the woman desires to become pregnant.

Desired Outcome

Menorrhagia therapy should reduce menstrual blood flow, improve the patient's quality of life, and defer the need for surgical intervention. Table 89–2 lists the agents and their recommended dosing for menorrhagia management. Figure 89–3 presents an algorithm for menorrhagia treatment.

General Approach to Treatment

Several treatment options exist for menorrhagia. Initial and subsequent treatment options should be thoughtfully chosen in an effort to avoid surgery.

Nonpharmacologic Therapy

Nonpharmacologic interventions for menorrhagia include surgical procedures that are generally reserved for patients not responding

TABLE 89-3 Significant Pharmacologic Properties and Significant Drug–Drug and Drug–Food Interactions of Therapeutic Agents for Selected Menstrual Disorders

Therapeutic Agent/ Drug Class	Mechanism of Action/Role in Particular Menstrual Disorders	Significant Side Effects	Significant Drug–Drug, Drug–Food, Drug–Disease Interactions
Clomipramine	Exact mechanism in PMDD unknown	Dry mouth, fatigue, vertigo, sweating	
Combination OCs	Exogenous estrogen and progesterone that suppresses FSH and LH production and thus inhibits ovulation	Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, gastrointestinal upset, headache, peripheral edema	St. John's wort contributes to altered menstrual bleeding
	Can be used to reduce menstrual flow (menorrhagia, dysmenorrhea), and control menstrual cycle (anovulatory bleeding secondary to hypoestrogenism)		Rifampin induces estrogen metabolism, possibly contributing to treatment failure Sulfa-containing drugs may contribute to increased photosensitivity
CEE	Estrogen replacement for hypoestrogenic states leading to anovulatory bleeding	As noted for combination OC	Same as OCs
Dopamine agonists (bromocriptine, cabergoline)	Suppresses prolactin production from pituitary tumors such that resumption of normal FSH and LH production occurs	Hypotension, nausea, constipation, anorexia, Raynaud's phenomenon	Inhibit CYP3A4 and are metabolized by CYP3A4 St. John's wort induces CP3A4; coadministration may lead to treatment failure
Drospirenone-containing OCs	Progesterone with antimineralocorticoid and antiandrogenic properties; decreases emotional lability associated with PMDD	As noted for combination OC; increased risk of hyperkalemia	Same as OCs Coadministration of potassium-sparing diuretics or diets high in potassium may contribute to increased serum potassium concentrations, particularly in women with renal dysfunction
Ethinyl estradiol transdermal patch	Same as combination OCs and CEE	As noted for combination OC; however, lesser effects on serum cholesterol concentrations because patch avoids first-pass metabolism	Same as OCs
Leuprolide	GnRH agent that contributes to suppression of FSH and LH and ultimately a reduction in estrogen and progesterone, inhibiting the normal menstrual cycle/ hormonal fluctuations	Hot flashes, night sweats, headache, nausea	
Levonorgestrel-containing IUD	Suppresses FSH and LH and ultimately estrogen and progesterone, inhibiting the usual growth of the endometrium	Irregular menses, amenorrhea	
MPA (oral and depot)	Suppresses FSH and LH and ultimately estrogen and progesterone, inhibiting the usual growth of the endometrium	Edema, anorexia, depression, insomnia, weight gain or loss, increase in serum total and LDL cholesterol, may reduce HDL cholesterol	
Metformin	Inhibits hepatic glucose production and increases sensitivity of tissues to insulin, thus reducing insulin resistance	Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis (rare)	IV contrast dye may increase the risk of lactic acidosis; stop metformin 1 day prior and restart when renal function is normal and stabilized following the IV dye
NSAIDs	Inhibits prostaglandin release that occurs with menses, thus reducing inflammatory response contributing to dysmenorrhea	Gastrointestinal upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness	
SSRIs	Exact mechanism in PMDD unknown	Sexual dysfunction (reduced libido, anorgasmia), insomnia, sedation, hypersomnia, nausea, diarrhea	
Thiazolidinediones	Increases peripheral tissue sensitivity to insulin, thus reducing insulin resistance	Weight gain, increase in total, LDL, and HDL cholesterol, edema, headache, fatigue, hepatic injury (rare)	
Tranexamic acid	Antifibrinolytic effects by reversibly blocking lysine binding sites on plasminogen, preventing fibrin degradation and a reduction in menstrual blood loss	Nausea, vomiting, diarrhea, dyspepsia	
Venlafaxine	Exact mechanism in PMDD unknown		

CEE, conjugated equine estrogen; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HDL, high-density lipoprotein; IUD, intrauterine device; LDL, low-density lipoprotein; LH, luteinizing hormone; MPA, medroxyprogesterone acetate; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitor.

Data from references 7, 10, 11, 14, 15, 20, 23, 27, 28.

TABLE 89-4 Expected Outcome Measures for Select Menstrual Bleeding Disorders

Menstrual Disorder	Expected Outcome Measures: Specific Monitoring Parameters and Frequency of Monitoring
Amenorrhea	Patient should return after one month of treatment to evaluate whether menses has resumed. Menses should resume within 1–2 months of therapy. If amenorrhea has been long-standing and secondary to a hypoestrogenic condition, preservation/improvement of BMD is warranted. A baseline BMD test may be desirable; repeat test no sooner than 1–2 years. If amenorrhea is secondary to high prolactin levels, serum prolactin levels should be measured at baseline and weekly with dosage increases until response (resumption of menses) is observed; consider discontinuation of therapy after 6–12 months of menses and serum prolactin concentrations have normalized. In young women who have primary amenorrhea, normal breast development should occur over a time frame of several months of therapy.
Menorrhagia	Amount of blood lost with menses should be reduced (monitor decline in number of times feminine hygiene products such as pads and tampons require changing during menses) as observed within 1–2 menstrual cycles of therapy. Patient should return for evaluation after one full menstrual cycle of therapy. Hemoglobin/hematocrit should be measured at baseline and within 3 months of beginning therapy. Annual gynecologic examination should be performed in women receiving hormonal agents for treatment of menorrhagia. Serum lipid concentrations should be measured within 3–6 months of starting the hormonal regimen and repeated per national lipid guidelines as appropriate. Blood pressure should be measured at baseline and within 4–6 weeks of beginning any hormonal agents; repeat blood pressure measurements per national hypertension guidelines as appropriate.
Anovulatory bleeding	Patients should return for follow up within 1 week to evaluate alleviation of acute bleeding when present. Acute severe bleeding should decline within 10 days of therapy onset. Ovulation, if desired, can be measured via daily basal body temperature evaluation, use of home ovulation predictor kits, and serum FSH/LH measurements at the time of suspected ovulation. If resumption of ovulation is desired by women receiving metformin, it is important to be aware that metformin may contribute to resumption of ovulation after 3–6 months of therapy. In women with PCOS, baseline and repeat measurements of blood pressure, serum lipids, and blood glucose should be assessed per national guidelines to monitor for the development, presence, or progression of hypertension, hyperlipidemia, and diabetes. When OCs are used for control of abnormal uterine bleeding, improvement in the pattern of abnormal bleeding should occur within 1–2 menstrual cycles of therapy. Annual gynecologic examinations should be performed; serum lipid concentrations should be measured within 3–6 months of starting the OC and repeated per national lipid guidelines. Blood pressure should be measured at baseline and within 4–6 weeks of beginning any hormonal agents; repeat blood pressure measurements per national hypertension guidelines as appropriate.
Dysmenorrhea	Patient should return for evaluation of reduction in or absence of pelvic pain related to menses after 1–2 menstrual cycles of therapy. In addition, reduction in time lost from work/school and improved quality of life should be observed after a full 1–3 menstrual cycles of OC therapy. If NSAIDs are used, improvement in pain should be observed within hours of the dose.
PMDD	Reduction in or absence of initial symptoms and improved quality of life may be observed within 1–3 menstrual cycles of therapy. SSRIs have resulted in significant improvement after one cycle of treatment. If an OC containing drospirenone is used, serum potassium should be monitored within the first month of use if the woman is also receiving agents that predispose her to increased serum potassium concentrations. An annual gynecologic examination should be performed; serum lipid concentrations should be measured within 3–6 months of starting the OC and repeated per national lipid guidelines as appropriate. Blood pressure should be measured at baseline and within 4–6 weeks of beginning any hormonal agents; repeat blood pressure measurements per national hypertension guidelines as appropriate.

BMD, bone mineral density; FSH, follicle-stimulating hormone; LH, luteinizing hormone; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive; PCOS, polycystic ovary syndrome; PMDD, premenstrual dysphoric disorder; SSRI, selective serotonin reuptake inhibitor.

Data from references 4, 5, 27, 31–36.

to pharmacologic treatment. These interventions vary from conservative endometrial ablation to hysterectomy.[37]

Pharmacologic Therapy

Among the agents used to treat menorrhagia, the nonsteroidal antiinflammatory drugs (NSAIDs) have the advantage of administration only during menses. NSAID use is associated with a 20% to 50% reduction in blood loss in 75% of treated women.[15] In some patients, as much as an 80% reduction in blood loss has been observed.[15]

For women desiring to avoid pregnancy, OC use is beneficial for menorrhagia and should be considered. A 43% to 53% reduction in menstrual blood loss has been observed in 68% of menorrhagia patients treated with OCs containing greater than or equal to 35 mcg of estradiol.[15] 5 The reduction in menorrhagia-related blood loss with use of NSAIDs and OCs is directly proportional to the amount of pretreatment blood loss.[15]

Another menorrhagia treatment option is the levonorgestrel-releasing intrauterine device (IUD). This is a very effective treatment that consistently reduces menstrual flow by at least 90%.[15,38] In particular, an 86% reduction in blood loss has been observed after 3 months of use; as much as 97% after 12 months.[39] Its use has also resulted in postponing or cancelling scheduled endometrial ablation surgery or hysterectomy. Sixty percent of treated patients avoided hysterectomy when employing this treatment option,[38,40,41] and its therapeutic efficacy is similar to endometrial ablation up to 2 years following treatment.[19]

Progesterone therapy either during the luteal phase of the menstrual cycle or for 21 days, starting on day 5 after onset of menses, results in a 32% to 50% reduction in menstrual blood loss.[15] However, progesterone use is not superior to other medical treatments, including the NSAIDs.[15]

Tranexamic acid was recently approved in the United States for primary menorrhagia treatment. Its use is associated with a significant 40% to 50% reduction in menstrual blood loss.[17]

Drug Treatments of First Choice For women who have menorrhagia associated with ovulatory cycles and do not desire hormonal therapy and/or contraception, NSAIDs during menses is a reasonable choice, in the absence of any contraindications or gastrointestinal illnesses such as peptic ulcer disease or gastroesophageal reflux disease. This choice is convenient (only taken during menses) and comparatively inexpensive. For women desiring contraception, it is reasonable to start with either an OC or the levonorgestrel-releasing IUD. Either choice is acceptable for both nulligravid and multiparous women who desire a long-term reversible form of contraception.[38] Given cost-effectiveness data, the levonorgestrel-releasing IUD is the best first-line choice for women desiring contraception.[42] Clinical trial data illustrate a higher failure rate with the OCs (62.5%) compared with the levonorgestrel-releasing IUD (34%) as the primary treatment method.[42]

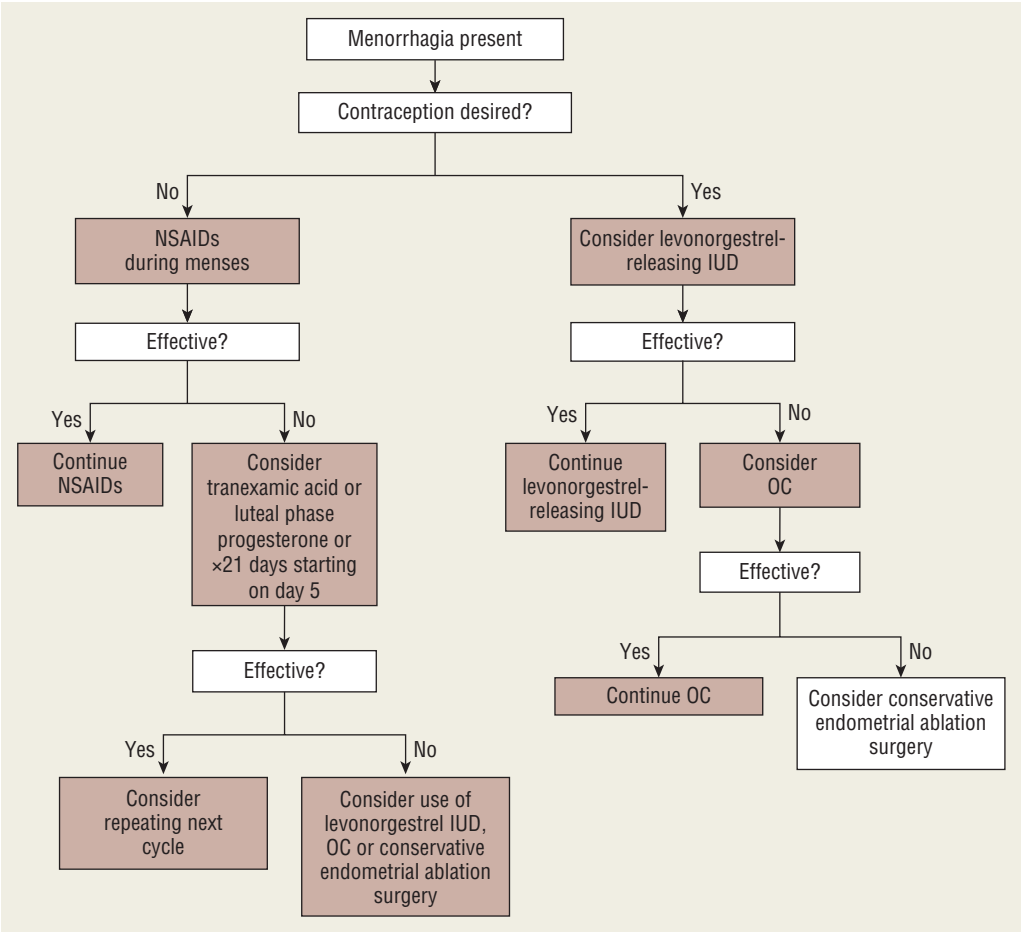

FIGURE 89-3. Treatment algorithm for menorrhagia. (IUD, intrauterine device; NSAIDs, nonsteroidal antiinflammatory drugs; OC, oral contraceptive.)

Alternative Drug Treatments Given their side effects, reduced efficacy compared with the first-line agents, and/or cost, use of oral progesterone and depot MPA should be reserved. Tranexamic acid is another treatment option. In comparison to luteal phase oral progesterone, tranexamic acid results in a significantly greater reduction in menstrual blood loss and greater relief of patient-reported symptoms.[15] Its use has been associated with a significant improvement in quality of life and high patient satisfaction following three cycles of use.[17,20]

Special Populations Although historically it was believed that IUD use should be avoided in nulliparous women, ⑥ the American College of Obstetricians and Gynecologists (ACOG) indicate that both nulliparous and multiparous women at low risk of sexually transmitted diseases are good candidates for IUD use.[38] Therefore, any of the treatments discussed are options in any female presenting with menorrhagia. Dosage adjustment for tranexamic acid is recommended for reduced renal function. Women with serum creatinine between 1.4 and 2.8 mg/dL (124 and 248 μmol/L) should receive only 1,300 mg by mouth twice daily; women with serum creatinine between 2.9 and 5.7 mg/dL (256 and 504 μmol/L) should receive 1,300 mg by mouth once daily; those with serum creatinine above 5.7 mg/dL (504 μmol/L) should receive 650 mg by mouth once daily.

Drug Class Information Table 89–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of the agents for menorrhagia management.

PHARMACOECONOMIC CONSIDERATIONS

The levonorgestrel-releasing IUD is the most cost-effective option when compared to surgical management and OCs in OC-naïve women and women who had received OCs with or without a response.[42]

EVALUATION OF THERAPEUTIC OUTCOMES

Table 89–4 illustrates the expected outcomes and specific monitoring parameters for the treatment modalities used in menorrhagia management.

ANOVULATORY BLEEDING

⑦ Anovulatory bleeding is the standard terminology used to describe bleeding from the uterine endometrium as a result of a dysfunctioning menstrual system, specifically excluding an anatomic lesion of the uterus.[1,32] Anovulatory bleeding is also referred to as dysfunctional or irregular uterine bleeding.

EPIDEMIOLOGY

Anovulatory bleeding is the most common form of noncyclic uterine bleeding.[4] PCOS is the most common cause, with prevalence rates ranging from 5% to 10% in various reports, depending on the diagnostic criteria used (e.g., PCOS-NIH[43] or PCOS-Rotterdam[44]).[1,5,45,48] In fact, PCOS is the most common

endocrine abnormality among U.S. women of reproductive age.[46] 8 PCOS can present as a variety of menstruation disorders, including amenorrhea, menorrhagia, and/or anovulatory bleeding. Although its exact definition continues to evolve, it is a disorder of androgen excess that often includes polycystic ovarian morphology and ovulatory dysfunction. It is a significant risk factor for the metabolic syndrome, type 2 diabetes, dyslipidemia, hypertension, and possibly cardiovascular disease.[22,47,48] PCOS is a common cause of ovulation dysfunction in adult women.[22] Other common causes in adult women include hyperprolactinemia, hypothalamic amenorrhea, also known as hypogonadotropic hypogonadism, premature ovarian failure, and thyroid dysfunction.[1,32]

ETIOLOGY

When considering the etiology of anovulatory bleeding, the patient's age must be considered. All patients presenting with abnormal bleeding should be evaluated for pregnancy. Most adolescents will experience physiologic anovulatory cycles in the first few years following menarche because their hypothalamic–pituitary–gonadal axis is still maturing. However, if an adolescent has not developed regular menstrual cycles within 5 years of menarche, further evaluation for the cause, such as PCOS, should be considered.[49] Anovulatory cycles may "unmask" an underlying bleeding disorder. When irregular menses is associated with significant bleeding, an inherited bleeding disorder should be a considered cause, especially in adolescence.[6,32] Women experiencing anovulation in their reproductive years should be evaluated for pathologic causes, including PCOS, thyroid dysfunction, hyperprolactinemia, primary pituitary disease, premature ovarian failure, hypothalamic dysfunction, disordered eating, adrenal disease, and androgen-producing tumors. Women in their perimenopausal years may experience "physiologic" anovulatory cycles because of intermittently declining estrogen levels. Regardless of age, evaluation for endometrial hyperplasia and/or endometrial cancer should be considered when a woman experiences excessive bleeding with anovulatory cycles. When considering the etiology of anovulation, it is common for several conditions to coexist (e.g., PCOS and hypothyroidism), each contributing to the woman's constellation of symptoms. All common etiologies should be considered when beginning to evaluate anovulation.[1]

PATHOPHYSIOLOGY

Normal menstrual cycles occur through a complex interaction of the hypothalamus, pituitary gland, ovaries, and endometrium (Fig. 89–1). In an ovulatory cycle, the ovary produces a mature, estrogen-secreting follicle in response to FSH release from the pituitary. The endometrium proliferates under the influence of this estrogen production. At a critical level of estrogen concentration, the pituitary responds by producing an "LH surge," which creates a cascade of ovarian events, culminating in ovulation. Upon oocyte release, the follicle becomes a progesterone-producing corpus luteum. The endometrium "organizes" into secretory endometrium in the presence of adequate progesterone. If conception and implantation do not occur, corpus luteum involution causes a decline in estrogen and progesterone leading to predictable, organized menstrual flow as the endometrium sloughs.

If ovulation does not occur, progesterone is not produced, and the endometrium will continue to proliferate in an "unorganized" fashion under the influence of continued estrogen production. Eventually the endometrium will become so thick that it can no longer be supported by continued estrogen production. This results in unorganized, sporadic sloughing of the endometrium, characteristic of the unpredictable and heavy bleeding of anovulation. Anovulation has several etiologies. In adolescence, hypothalamic–pituitary axis immaturity contributes to the absence of the LH surge required for ovulation. In the anorexic patient, the hypothalamus loses much of its pulsatile GnRH release, leading to low levels of FSH and LH, enough for estrogen production but not enough to induce ovulation.

CLINICAL PRESENTATION OF ANOVULATORY BLEEDING

General

- Patients may or may not be in acute distress.

Symptoms

- Irregular, heavy, or prolonged vaginal bleeding, perimenopausal symptoms (hot flashes, night sweats, vaginal dryness)

Signs

- Acne, hirsutism, obesity

Laboratory Tests

- If PCOS is suspected, consider free or total testosterone fasting glucose, fasting lipid panel
- If perimenopause is suspected, measure FSH
- Thyroid-stimulating hormone

Other Diagnostic Tests

- If the patient is older than 35 years, endometrial biopsy
- Pelvic ultrasound to evaluate for polycystic ovaries
- If perimenopause is suspected, measure FSH

TREATMENT

Optimizing anovulatory bleeding therapy depends on accurate identification of the disorder's cause(s). The treatment options for anovulatory bleeding are wide and varied.

Desired Outcome

Control of excessive bleeding in the short-term is paramount. Longer-term goals of therapy include restoring the natural cycle of orderly endometrial growth and shedding,[32,50] decreasing anovulation complications (e.g., osteopenia, infertility), and improving overall quality of life. Table 89–2 identifies the agents used to manage anovulatory bleeding and their recommended doses.

General Approach to Treatment

Although the appropriate primary treatment choice for anovulatory bleeding depends on the accurate diagnosis of its cause and identification of desired outcomes, additional treatment may be necessary to manage other signs and symptoms. Treatment to resolve anovulatory bleeding should be initiated and any underlying menorrhagia should be managed.

Nonpharmacologic Therapy

Nonpharmacologic treatment options for anovulatory bleeding depend on the underlying cause. In a woman of reproductive age with PCOS, weight loss may be beneficial.[22] In women who have completed childbearing or who have not responded to medical management, endometrial ablation or resection and hysterectomy are surgical options. Procedure choice involves shared decision making with the patient. In the short term, ablation results in less morbidity and shorter recovery periods. However, a significant number of women eventually undergo hysterectomy in the subsequent 5 years.[32]

Pharmacologic Therapy

Estrogen is the recommended treatment for managing acute severe bleeding episodes because it promotes endometrial stabilization.[50] Following its initial use to control acute bleeding episodes, therapy continuation may be necessary to prevent future occurrences. OC use fulfills this role and contributes to predictable menstrual cycles.

OCs prevent recurrent anovulatory bleeding by providing a progestin and suppressing ovarian hormones and adrenal androgen production. They also, indirectly, increase sex hormone–binding globulin (SHBG). SHBG binds androgens and reduces their circulating free concentrations. For women with high androgen levels and its related signs such as hirsutism (e.g., those with PCOS), OCs containing less than or equal to 35 mcg of ethinyl estradiol and a progesterone that exhibits minimal androgenic side effects (e.g., norgestimate and desogestrel) or with antiandrogenic effects (e.g., drospirenone) may be desirable.[22]

In women with contraindication(s) to estrogen or in whom the side effects are unacceptable, progesterone-only products are an option. They should be strongly considered for women experiencing menorrhagia associated with anovulatory bleeding.[51] In women with PCOS, depot and intermittent oral MPA provide endometrial protection through endometrial shedding.[5] If pregnancy is not a desired outcome of treatment, another progesterone option is placement of a levonorgestrel-containing IUD.[32,51]

Metformin and the thiazolidinediones, including pioglitazone and rosiglitazone, improve insulin sensitivity. In patients with PCOS, this contributes to reduced circulating androgen concentrations, increased ovulation rates,[5,52,53] and improved glucose tolerance.[5,22] These improvements occur due to the SHBG increase that occurs via increased insulin sensitivity. 9 Metformin and thiazolidinedione use for anovulatory bleeding associated with PCOS is beneficial not only for anovulatory bleeding and fertility but also for improving glucose tolerance and other metabolic parameters that contribute to cardiovascular risk.[5,55] For women desiring pregnancy, metformin is pregnancy category B, and pioglitazone and rosiglitazone are category C.

CLINICAL CONTROVERSY

The overall role of metformin in treating PCOS, particularly its duration of therapy, remains controversial. For ovulation induction, data illustrate that metformin is highly effective in both clomiphene citrate–resistant patients and patients using it as initial therapy.[52,53] Its use throughout pregnancy has been associated with a reduction in early pregnancy loss rates.[54] The presence of dyslipidemia and hyperinsulinemia increases the long-term risk for developing cardiovascular disease in PCOS patients. Current research indicates that metformin should be considered to reduce cardiovascular risk in these women.[55] More research is needed to definitively identify the role(s) of metformin in PCOS.

If the treatment goal is improved fertility via ovulation induction, clomiphene citrate is an option. Treatment with 50 mg/day for 5 days can be initiated between menstrual cycle days 3 and 5. This often occurs after inducing withdrawal bleeding with a progesterone such as MPA 10 mg daily orally for 10 days. If ovulation does not occur with this dose of clomiphene, a dose of 100 mg/day is warranted. In rare instances, it may be increased by 50 mg increments up to 250 mg/day.

Drug Treatments of First Choice As with many menstruation-related disorders, there is not one universal treatment option of first choice for anovulatory bleeding. Rather, the treatment(s) chosen depends on accurate etiologic diagnosis as well as identification of the desired treatment outcome(s).

OCs are the first-choice treatment in women with anovulatory bleeding.[22] While controversial, the use of OCs containing ethinyl estradiol and a progesterone with minimal androgenic or antiandrogenic effects is effective for cycle control and minimizing the androgenic signs and symptoms of PCOS.[21,48]

CLINICAL CONTROVERSY

OCs are very effective for managing the acne and hirsutism that accompany PCOS; they also suppress ovarian androgen production and increase sex hormone binding globulin, thus reducing testosterone free concentrations. Controversy regarding their use in PCOS exists secondary to their potential adverse effects on insulin resistance, glucose tolerance, vascular reactivity, and coagulability.[22] Additional, longer-term clinical trials will identify whether the benefits of these agents outweigh the risks.

Relative to anovulation in women with PCOS, insulin-sensitizing agents, including metformin and the thiazolidinediones, improve ovulatory frequency and metabolic parameters. Clomiphene use may further assist in achieving ovulation induction.

More recent data supports even further the use of metformin compared with clomiphene for ovulation induction.[52,53] Metformin for ovulation induction[52] as well as its use throughout pregnancy[54] in women with PCOS has been associated with reduced miscarriage rates in this patient population.

Special Populations Anovulatory cycles are fairly common in the perimenarchal reproductive years. Ovulation typically is established 1 year or more following menarche. Anovulatory bleeding occurring in this population may be excessive. If excessive bleeding occurs, the patient should be evaluated for bleeding disorders. The prevalence of bleeding disorders, including von Willebrand disease, prothrombin deficiency, and idiopathic thrombocytopenia purpura, in this population ranges from 5% to 24%.[6]

If identified, the specific bleeding disorders should be treated. Acute severe bleeding can be managed with high-dose estrogen. OCs containing less than or equal to 35 mcg of ethinyl estradiol is a first-line treatment in adolescents with chronic anovulation.[50]

Drug Class Information Table 89–3 identifies the significant pharmacologic properties, common adverse events, and clinically significant drug–drug and drug–food interactions of agents used to treat anovulatory bleeding.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 89–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used to manage anovulatory bleeding.

DYSMENORRHEA

Dysmenorrhea is one of the most commonly encountered gynecologic complaints. It is defined as crampy pelvic pain occurring with or just prior to menses. Primary dysmenorrhea implies pain in the

setting of normal pelvic anatomy and physiology. Secondary dysmenorrhea is associated with underlying pelvic pathology.[14]

EPIDEMIOLOGY

Dysmenorrhea prevalence rates range from 16% to 90%.[33,34] Its presence may be associated with significant interference in work and school attendance. Risk factors include young age, heavy menses, nulliparity, early menarche, and cigarette smoking.[9,12]

ETIOLOGY

For most patients, dysmenorrhea is associated with normal ovulatory cycles and normal pelvic anatomy. This is referred to as primary, or functional, dysmenorrhea. However, in approximately 10% of the adolescents and young adults presenting with painful menses, an underlying anatomic or physiologic cause exists.[12]

PATHOPHYSIOLOGY

The most significant mechanism for primary dysmenorrhea is the release of prostaglandins and leukotrienes into the menstrual fluid, initiating an inflammatory response and possibly vasopressin-mediated vasoconstriction.[9,12,29] Causes of secondary dysmenorrhea include cervical stenosis, endometriosis, pelvic infections, pelvic congestion syndrome, uterine or cervical polyps, uterine fibroids, genital outflow tract obstructions, and pelvic adhesions.[12,34] Pregnancy and miscarriage must be considered in the presentation of dysmenorrhea.

CLINICAL PRESENTATION OF DYSMENORRHEA

General

- Patient may or may not be in acute distress, depending on the level of menstrual pain experienced.

Symptoms

- Patients complain of crampy pelvic pain beginning shortly before or at the onset of menses. Symptoms typically last from 1 to 3 days.

Laboratory Tests

- Pelvic examination should be performed to screen for sexually transmitted diseases as a cause of the pain in sexually active females.
- Gonorrhea, *Chlamydia* cultures or polymerase chain reaction, wet mount

Other Diagnostic Tests

- Pelvic ultrasound can be used to identify potential anatomic abnormalities such as masses/lesions or to detect ovarian cysts and endometriomas.

TREATMENT

Initial treatment choice is influenced by whether or not the woman desires pregnancy. Nonpharmacologic options have been studied and observed to be as effective as some existing pharmacologic options.

Desired Outcome

Medical management of dysmenorrhea should relieve the pelvic pain and result in reducing lost school and work days. Table 89–2 identifies the agents used to manage dysmenorrhea and their recommended doses. Figure 89–4 shows a treatment algorithm for dysmenorrhea management.

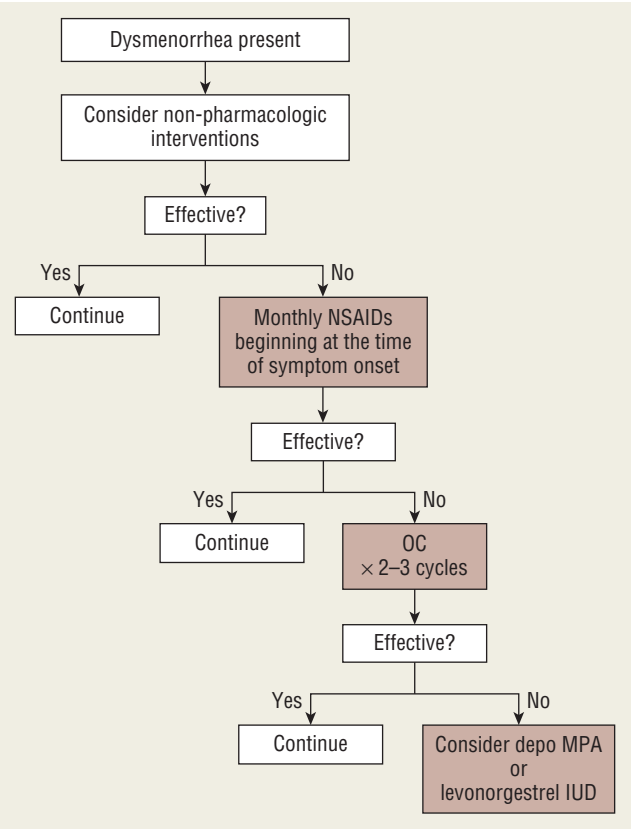

FIGURE 89-4. Treatment algorithm for dysmenorrhea. (IUD, intrauterine device; MPA, medroxyprogesterone acetate; NSAIDs, nonsteroidal antiinflammatory drugs; OC, oral contraceptive.)

General Approach to Treatment

A variety of effective treatment options for dysmenorrhea are available, including nonhormonal and hormonal pharmacologic options and noninvasive nonpharmacologic options. Treatment choice is influenced by the desire for contraception, the patient's level of sexual activity, potential for adverse effects, and cost.

Nonpharmacologic Therapy

Several nonpharmacologic interventions are used for managing dysmenorrhea. Among these, topical heat therapy, exercise, and a low-fat vegetarian diet have been shown to reduce dysmenorrhea intensity.[12,13,14,33] Dietary changes may shorten dysmenorrhea duration. Topical heat application via an abdominal patch worn for 12 consecutive hours/day is as effective as 400 mg of ibuprofen dosed 3 times daily.[56] Because topical heat, exercise, and dietary changes do not impart systemic effects, they are associated with little to no risk compared to the pharmacologic options. Nonpharmacologic options that are reserved for use following a failed trial of pharmacologic interventions include transcutaneous electric nerve stimulation, acupressure, and acupuncture.[14,33]

Pharmacologic Therapy

Given the role of prostaglandins in dysmenorrhea pathophysiology, NSAIDs are the initial treatment of choice. These agents do not differ in efficacy. The most commonly used agents are naproxen and ibuprofen.

All NSAIDs have a propensity for causing gastrointestinal distress and ulceration; their administration with food or milk minimizes these effects. In women who have a history of NSAID-induced gastric effects, the use of celecoxib, a cyclooxygenase 2 (COX-2) inhibitor, is an alternative.[12,16] Choice of one agent over another may be based on cost, convenience, and patient preference.[14] Some research suggests that NSAID therapy should begin at the onset of menses or perhaps even the day before and continued around the clock instead of waiting until symptom onset. The data substantiating this is weak.[33] If an NSAID or celecoxib use is contraindicated or not desired, hormonal agents should be considered. Acetaminophen is inferior to NSAID in treatment of this disorder.[14,33]

CLINICAL CONTROVERSY

Contrary to what often occurs in practice, the data substantiating that dysmenorrhea is best managed when treatment is initiated prior to the start of menses and continued around the clock is weak.[33] This is not a "high stakes" controversy given that NSAIDs are relatively inexpensive and the lower risk for gastrointestinal effects given the age of the population of patients affected by this disorder. There is a lack of clinical trial data supporting the optimal dosing regimen for dysmenorrhea, thus improving the patient's quality of life.

OCs improve dysmenorrhea by inhibiting endometrial tissue proliferation which reduces endometrial-derived prostaglandins that cause the pelvic pain.[12,13,33] Significant improvements in mild, moderate, and severe dysmenorrhea have been noted with OCs. Evidence supporting monophasic versus multiphasic OC regimens, however, is lacking. And while the use of extended-cycle OCs would be desirable for this purpose, data illustrating their superiority over traditional monthly OCs does not currently exist.

Depot MPA can be considered for dysmenorrhea treatment. Its efficacy is secondary to its ability to render most patients amenorrheic within 6 to 12 months of use.[14,33] Because the pelvic pain of dysmenorrhea is related to the prostaglandins released during menses, in the setting of amenorrhea the underlying cause of dysmenorrhea is removed.

Another progesterone product used for dysmenorrhea management is the levonorgestrel-releasing IUD. Observational data indicate its ability to reduce dysmenorrhea from 60% to 29% after 3 years of use.[12,14] As observed with depot MPA, this reduction likely is secondary to its effect in reducing menstrual flow.

Drug Treatments of First Choice Several factors influence the choice of first-line treatment for dysmenorrhea. If contraception is desired, then a hormonal option may be considered taking into account cost, adherence issues, and side effects. If contraception is not desired, then NSAID use would be desirable from cost and convenience standpoints. If NSAIDs are not tolerated, celecoxib could be recommended. In patients for whom OCs, NSAIDs, or celecoxib is not an option, topical heat should be considered.

Special Populations Dysmenorrhea is common in adolescent females. The treatment measures used for adult patients are also appropriate for adolescents. Although NSAIDs, topical heat, and OCs are among the top choices, use of the levonorgestrel IUD is also an option.[38]

Drug Class Information Table 89–3 identifies the significant pharmacologic properties, common adverse events, and clinically relevant drug–drug and drug–food interactions of agents used to treat dysmenorrhea.

PHARMACOECONOMIC CONSIDERATIONS

For women with third-party coverage for prescriptions, most OCs and the higher NSAID doses used for dysmenorrhea would be covered. For women without such coverage, the OC cost may be prohibitive. Generic forms of NSAIDs in over-the-counter strengths can be considered and are less expensive than marketed topical heat products, such as transdermal topical heat patches. Topical heat can be administered inexpensively via a reusable heating pad or hot water bottle. However, these products are not convenient to use.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 89–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in the management of dysmenorrhea.

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

PMS is a constellation of symptoms including mild mood disturbances and physical symptoms occurring prior to menses and resolving with menses initiation. It is distinct from PMDD.

EPIDEMIOLOGY

Up to 75% of menstruating women experience PMS symptoms.[57] However, a spectrum of premenstrual mood disturbances exists, and PMDD is the most severe. Approximately 3% to 8% of women have PMDD.[25,57]

ETIOLOGY AND PATHOPHYSIOLOGY

PMDD is a complex psychiatric disorder with multiple biological, psychological, and sociocultural determinants.[58] Although cyclic hormonal changes are in some way related to PMS and PMDD, the association is neither linear nor simple. When ovulation is suppressed medically or surgically, symptoms improve. Some evidence suggests that PMS and PMDD symptoms are related to low levels of the centrally active progesterone metabolite allopregnanolone in the luteal phase and/or lower cortical γ-aminobutyric acid levels in the follicular phase.[58] Women with PMS and PMDD may have enhanced sensitivity to progesterone.[35] Studies of the relationship between PMS and PMDD and testosterone levels are conflicting.[58] A number of studies suggest a link between PMS and PMDD and low serotonin levels.[35,58] Despite similar affective symptoms, hypothalamic–pituitary–adrenal (HPA) axis function in PMS and PMDD is distinct from that seen in major depressive disorder. Specifically, women with PMS show a decrease in stimulated HPA axis response, whereas this response is increased in women with major depressive disorder.[59] Although several cross-cultural studies suggest that PMS' physical symptoms are consistent across cultures, the negative affective symptoms are part of the negative "menstrual socialization" in Western culture.[1,58]

CLINICAL PRESENTATION OF PMDD

A summary of the American Psychiatric Association's criteria for PMDD is as follows:[1,58]

- Symptoms are temporally associated with the last week of the luteal phase and remit with onset of menses.
- At least five of the following symptoms are present: markedly depressed mood, marked anxiety, marked affective lability,

marked anger or irritability, decreased interest in activities, fatigue, difficulty concentrating, changes in appetite, sleep disturbance, feelings of being overwhelmed, and physical symptoms, such as breast tenderness or bloating.

- One of the symptoms must be markedly depressed mood, anxiety, irritability, or affective lability.
- Symptoms interfere significantly with work and/or social relationships.
- Symptoms are not an exacerbation of another underlying psychiatric disorder.
- The criteria are confirmed prospectively by daily ratings over two menstrual cycles.

TREATMENT

Women experiencing PMS and PMDD symptoms miss significantly more work and school than do controls. They also report significant impairment of their ability to participate in social activities and hobbies and in their relationships with others.[60] Given this, the need for effective treatment modalities is clear.

Desired Outcome

PMS and PMDD interventions should alleviate the presenting symptoms and subsequently improve quality of life. Table 89–2 lists the various agents used in managing PMS and PMDD and their recommended dosing.

General Approach to Treatment

A treatment modality that is minimally invasive or without systemic effects is desired for initial therapy. Key to the successful choice of pharmacologic therapy for PMS and PMDD is having the patient chart her specific symptoms for at least 2 months.

Nonpharmacologic Therapy

Lifestyle interventions should be started and followed for 2 months while the patient charts her symptoms. Although these interventions lack significant supporting clinical trial data, anecdotal reports of efficacy exist. Some lifestyle changes for women with mild-to-moderate premenstrual symptoms include minimizing intake of caffeine, refined sugar, and sodium and increasing exercise.[23,57,61] Vitamin and mineral supplements, such as vitamin B_6 (50–100 mg daily) and calcium carbonate (1,200 mg daily), may help reduce the physical symptoms associated with PMS.[23,25] A clinical trial review concludes that the following options lack efficacy and safety data and should not be recommended: herbal medicines, homeopathic remedies, dietary supplements, relaxation, massage therapy, reflexology, chiropractic treatments, and biofeedback.[62]

Pharmacologic Therapy

If symptoms persist after 2 months of symptom charting and lifestyle modifications, pharmacologic therapy for PMDD management is warranted. Over the past decade, the selective serotonin reuptake inhibitors (SSRIs) have been studied significantly for this disorder.[26,63–65] Studies have revealed very positive results relative to most symptoms associated with PMDD. Other agents that have been studied and are alternatives include the selective serotonin–norepinephrine reuptake inhibitor venlafaxine, as well as OCs, tricyclic antidepressants, and GnRH agonists.

Drug Treatments of First Choice ⑩ The first-line pharmacologic treatment options for PMDD are the SSRIs.[57] Among this class of agents, data support the use of citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline. Whether to dose these agents continuously or only during the luteal phase[63] and the optimal duration of treatment[66] are still not evident.

CLINICAL CONTROVERSY

Current evidence supports SSRIs as first-line PMDD treatment, either dosed continuously or during the luteal phase alone. Some evidence suggests that SSRI dosing at symptom onset also may be effective.[67] The bulk of studies include women over age 18 years and with treatment durations not longer than 3 to 6 months.[57] Contrary to the excitement surrounding luteal phase dosing, a recent meta-analysis found in favor of the continuous dosing regimen for efficacy.[65] Relapse rates appear to be higher with shorter-duration treatment (4 months vs 12 months).[66] The most effective dosing strategy[63] (continuous, luteal phase, or symptom onset), most efficacious treatments in the adolescent versus perimenopausal populations, and the optimal treatment duration[66] are not evident and warrant further investigation.

The SSRIs are efficacious in more than half of the treated patients compared to less than 30% of those receiving placebo.[23,64,67] A meta-analysis reports 50% or greater symptom reduction with SSRI treatment compared to baseline.[65] Improvement often occurs during the first cycle of use.[23]

Alternative Drug Treatments The tricyclic antidepressant clomipramine has been studied for PMDD treatment. In placebo-controlled trials, both continuous daily dosing and luteal phase administration proved effective.[23] Compared with the SSRIs, however, clomipramine is not well tolerated due to its side effects. Venlafaxine has been studied on a continuous daily basis[68] and during the luteal phase.[69] Both venlafaxine regimens resulted in significant symptom improvement (compared to placebo) in more than 60% of treated women.

If treatment with an SSRI or another antidepressant such as clomipramine is unsuccessful, hormonal treatment with a GnRH agonist, such as leuprolide, can be considered.[23] Leuprolide improves premenstrual emotional symptoms as well as some physical symptoms, such as bloating and breast tenderness. However, its cost, the need for intramuscular administration, and its hypoestrogenism side effects (e.g., vaginal dryness, hot flashes, and bone demineralization) limit its use.

The use of a monophasic OC containing 20 mcg of ethinyl estradiol and 3 mg of drospirenone, a progesterone with antiandrogenic effects, improves premenstrual symptoms in women with PMDD.[24] As with the SSRIs, optimal treatment duration is unknown, and superiority to other OCs has not been established.

Drug Class Information Table 89–3 lists the significant pharmacologic properties, common adverse events, and clinically relevant drug–drug and drug–food interactions of the agents used to treat PMDD.

PHARMACOECONOMIC CONSIDERATIONS

The SSRIs as first-line treatment options for PMDD management are comparably priced overall; however, a generic formulation of fluoxetine is available. Emerging data on the most appropriate dosing regimens may contribute even further to a reduction in the cost of managing this disorder.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 89–4 lists the expected outcomes and specific monitoring parameters for the treatment modalities used in PMDD management.

CONCLUSIONS

Treatment success for the various menstruation-related disorders can be measured by the degree to which the care plan (1) relieves or reverses symptoms, (2) prevents or reverses the complications (e.g., osteoporosis, anemia, and infertility as noted with amenorrhea, menorrhagia, and anovulatory bleeding, respectively), and (3) minimizes side effects. The return of a regular menstrual cycle with minimal premenstrual symptoms or symptoms of dysmenorrhea is desirable. Depending on the desire for conception and subsequent therapy, this cycle may be ovulatory or anovulatory.

Once optimal therapy has been identified, the regimen can be continued as long as is deemed necessary. In amenorrhea, discontinuation of therapy may be warranted once menses resumes. In anovulatory bleeding, therapy may be discontinued once ovulatory menstrual cycles return. In menorrhagia, dysmenorrhea, and PMDD, optimal therapy may be continued until symptom resolution or until other health factors affect its continuation. For example, a woman taking OCs for menorrhagia or dysmenorrhea may discontinue them when she desires to become pregnant.

Symptom relief in dysmenorrhea should occur within hours of starting an NSAID or within the next menstrual cycle/menses if using OCs. Evaluate the patient for improvement of symptoms associated with amenorrhea, menorrhagia, anovulatory bleeding, or PMDD within one to two menstrual cycles. Ask patients at this visit about the type, frequency, and severity of current symptoms compared to their initial presenting symptoms. Refer patients with persistent symptoms for further medical evaluation to identify other underlying issues or complications.

Assess the effectiveness of therapy in resuming normal menstrual cycles with minimal related pain after an appropriate treatment interval (1–2 months). Assess improvement in quality of life measures such as physical, psychological, and social functioning and well-being. Evaluate the patient for adverse drug reactions, drug allergies, and drug interactions. Table 89–3 lists the common side effects that may occur and the monitoring required. Table 89–4 lists the specific expected outcome measures for each of the menstruation-related disorders discussed in this chapter.

ABBREVIATIONS

COX-2: cyclooxygenase 2

FSH: follicle-stimulating hormone

GnRH: gonadotropin-releasing hormone

HPA: hypothalamic–pituitary–adrenal axis

IUD: intrauterine device

LH: luteinizing hormone

MPA: medroxyprogesterone acetate

NSAID: nonsteroidal antiinflammatory drug

OC: oral contraceptive

PCOS: polycystic ovary syndrome

PMDD: premenstrual dysphoric disorder

PMS: premenstrual syndrome

SHBG: sex hormone–binding globulin

SSRI: selective serotonin reuptake inhibitor

CHAPTER 90

Endometriosis

DEBORAH A. STURPE

KEY CONCEPTS

1. Endometriosis should be suspected in any woman of reproductive age, including adolescents, with recurring cyclic or acyclic pelvic pain and/or subfertility.
2. The etiology of endometriosis is likely multifactorial; no single theory is satisfactory to explain all cases.
3. No physical examination findings or laboratory tests are considered diagnostic for endometriosis. A definitive diagnosis can be made only via surgical visualization of lesions. Confirmation of diagnosis is not necessary in all cases.
4. Treatment goals include improvement of painful symptoms and maintenance or improvement of fertility. Therapy is considered successful based on resolution of the patient's symptoms or achievement of pregnancy.
5. All medical therapies are equally efficacious in treating endometriosis-related pain based on available evidence. The choice among agents is determined primarily by side effect profile, cost, and individual patient response.
6. Endometriosis-related pain can be treated by medical or surgical therapy. Empirical medical therapy is likely more cost-effective and is recommended based on consensus guidelines.
7. Endometriosis-related infertility is unresponsive to medical therapy. Conservative surgical therapy is the preferred treatment.

Endometriosis is a common cause of chronic pelvic pain in women and is associated with infertility. Characterized by the presence of endometrial tissue outside the uterus, endometriosis is a chronic, recurring disease.

1 Endometriosis should be suspected in women, including adolescents, with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain. Therapy is targeted at relieving symptoms and improving fertility.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

The prevalence of endometriosis in the general population is estimated to be 5% to 10% of women.[1,2] Up to 70% of adult women and up to 50% of adolescents presenting with chronic pelvic pain may have endometriosis, and ~20% to 50% of women with infertility may have the disorder.[1,3–5] A genetic predisposition for endometriosis has been noted, as evidenced by disease rates that are up to seven times higher in primary relatives of affected women compared with the general population.[2]

CLINICAL CONTROVERSY

An association between endometriosis and ovarian cancer has been reported in the literature. Such reports often suggest that due to this association, aggressive treatment of endometriosis that includes surgical therapy should be recommended for many patients. However, this proposed association between endometriosis and cancer remains controversial. Consequently, data do not exist to enable evidence-based decision making in patients with endometriosis who may be at elevated risk for ovarian cancer.

ETIOLOGY

2 The etiology of endometriosis is unknown. Multiple mechanisms for development of lesions are likely, including theories of retrograde menstrual flow, coelomic metaplasia, lymphatic and vascular spread, and immunologic abnormalities.[1,2,4] Involvement of immune system factors in the development and progression of endometriosis is recognized. Findings of abnormal B- and T-cell function, decreased apoptosis, and altered levels of prostanoids, cytokines, growth factors, interleukins, and aromatase in endometrial lesions and peritoneal fluid of affected women support this theory.[1,2,6]

PATHOPHYSIOLOGY

PAIN AND INFERTILITY

Endometriosis-associated pain is likely secondary to generation of local inflammation by the endometrial lesions, bleeding from the endometrial tissue, and irritation or compression of nerve fibers by endometrial implants.[5,7] Estrogen has been found to contribute to endometriosis pain due to its role in helping to produce endometrial tissue and in stimulating release of inflammatory substances.[2]

The exact mechanism by which endometriosis reduces fertility is unknown, but it may result from distorted pelvic anatomy, altered peritoneal function, and altered endometrial receptivity that impairs implantation.[8]

DISEASE STAGING

The severity of disease can be classified according to the American Association of Reproductive Medicine staging system (stage I, mild, to stage IV, severe), but clinical utility of this staging system is limited because findings do not correlate with painful symptoms, nor does the staging system predict pregnancy rates.[9,10] Staging may be useful, however, in guiding decisions regarding prognosis and treatment for infertility.[9]

CLINICAL PRESENTATION

Symptoms

- The patient may be asymptomatic or complain of symptoms such as severe dysmenorrhea, deep dyspareunia, chronic pelvic pain (cyclic or acyclic), ovulation pain, cyclical or perimenstrual bowel and bladder complaints (e.g., GI disturbances, painful defecation, dysuria, and/or hematuria), chronic fatigue, or infertility.

Signs

- Findings on physical examination are best observed during menstruation and may include pelvic tenderness, tender uterosacral ligaments, enlarged ovaries, or a fixed, retroverted uterus.
- Findings on laparoscopic examination may range from a few small lesions located on the ovaries, serosal surfaces, or peritoneum to large cysts called endometriomas. Lesions are often described as: "powder burn" or "gunshot" lesions; dark brown, black, or blue lesions, nodules, and cysts; and "chocolate cysts" (endometriomas containing blood).

Diagnosis

- Definitive diagnosis can be made only by direct surgical visualization of endometrial lesions; however, treatment guidelines allow for nondefinitive diagnosis in patients presenting with chronic pelvic pain provided that other causes of pain are ruled out and that pain responds to first-line empiric therapies.

TREATMENT

The treatment of endometriosis varies depending on presenting symptoms, patient age, and desired outcome.

DESIRED OUTCOME

4 Treatment goals for endometriosis depend on the patient's presentation. Only women with active symptoms (pelvic pain, infertility, or both) require therapy. Depending on the primary complaint, the goals of endometriosis treatment are (a) minimization or removal of endometrial deposits, (b) prevention of disease progression, (c) minimization of associated pain, and (d) prevention or correction of associated infertility.

GENERAL APPROACH TO TREATMENT

5 The treatment of an asymptomatic patient with endometriosis consists of expectant management (watchful waiting) only because therapy is not indicated unless symptoms develop. For symptomatic patients, the foundation of therapy includes medical treatment, surgical treatment, or both. To date, no studies have directly compared medical and surgical treatment as first-line therapy. Furthermore, determining the optimal medical or surgical approach is difficult secondary to a paucity of well-designed, randomized, controlled trials. All commonly prescribed medical therapies relieve endometriosis-related pain by regressing lesions via induction of a pseudopregnancy or pseudomenopausal state but do not eradicate lesions or improve fertility. Therefore, the choice of initial therapy depends on multiple factors, such as the patient's primary complaint, the location and extent of disease, the desire for future fertility, the cost of therapy, contraindications to therapy, and potential side effects or complications of therapy.

6 Guidelines recommend empirical treatment of chronic pelvic pain suspected to be secondary to endometriosis with combined hormonal contraceptives (CHCs) or progestins for at least 3 months.[9,10] Empiric therapy with a gonadotropin-releasing hormone (GnRH) agonist can also be considered in women, but it is less optimal due to greater expense and toxicity.[10] The duration of medical therapy is typically limited to 6 months for drugs with higher toxicity profiles (e.g., danazol and GnRH agonists), but CHCs and progestins may be continued indefinitely.[10] Conservative surgical therapy is recommended for treating painful symptoms in women who do not respond to, or have contraindications to, medical therapy or patients with other compelling reasons for surgery. Definitive treatment for endometriosis involves nonconservative surgical therapy via bilateral salpingo-oophorectomy, with or without hysterectomy. This therapy should be reserved for women not desiring future fertility who accept the potential complications of surgically induced menopause. A general treatment algorithm for endometriosis-related pain is shown in Figure 90–1.

7 For women presenting with infertility as a primary complaint, first-line therapy involves surgical resection of endometrial lesions to restore normal anatomy, followed by watchful waiting.[8–10] Medical therapy alone is ineffective for endometriosis-related infertility and should be avoided.[9,10] For women in whom surgical intervention does not result in pregnancy, controlled ovarian stimulation with intrauterine insemination or in vitro fertilization may be recommended.[8–10] Pretreatment with a GnRH agonist for 3 to 6 months prior to in vitro fertilization cycles increases success rates.[9] Intrauterine insemination is preferred in women younger than age 35 with milder (stage I or II) disease, whereas in vitro fertilization is preferred in women over age 35 or those with more severe (stage III or IV) disease.[8]

NONPHARMACOLOGIC THERAPY: SURGERY

3 Laparoscopy is used in endometriosis as both a diagnostic and a therapeutic tool, and guidelines recommend removal of visible lesions at the time of initial diagnosis.[9] Although a significant percentage of women will experience recurrence of painful symptoms after surgery, the use of adjunctive medical therapy postoperatively is no longer recommended due to the lack of documented efficacy at 12 and 24 months.[9,10] Conservative

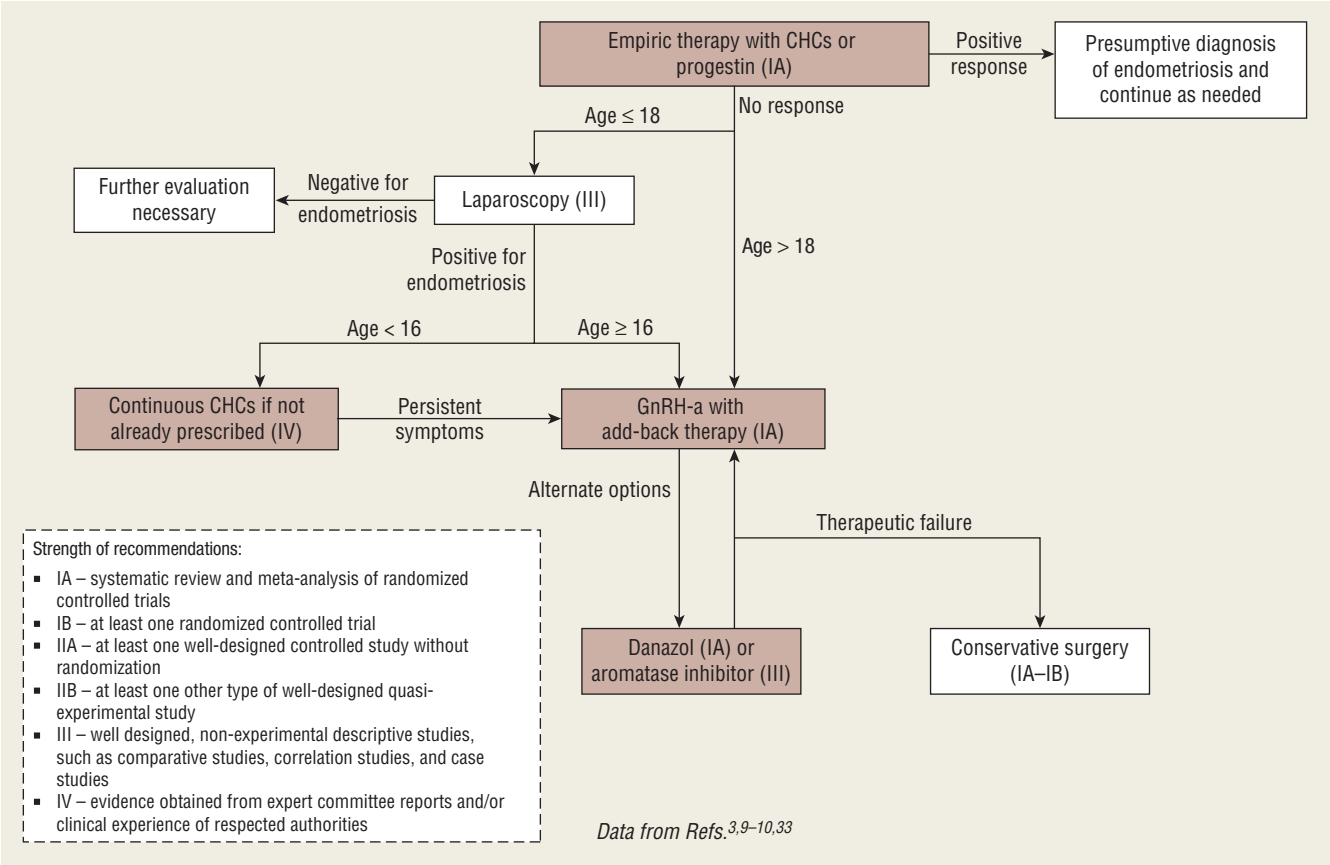

FIGURE 90-1. Treatment algorithm for cyclic/acyclic chronic pelvic pain and suspected endometriosis. CHC, combined hormonal contraceptive; GnRH-a, gonadotropin-releasing hormone agonist.

surgical therapy is also the primary treatment of endometriosis-associated infertility.

PHARMACOLOGIC THERAPY

Typically, pharmacologic therapy is the first choice for treatment of endometriosis-related pain to minimize risks from surgery. However, drug therapy will not treat endometriosis-related infertility.

Drug Treatments of First Choice

5 First-line therapy for endometriosis-associated pain includes CHCs or progestins.[3,9,10] These two drug classes are considered as effective as, and less costly and toxic than, other endometriosis treatments. The choice of agent depends on patient characteristics, such as the desire for contraception, pain patterns, and contraindications. Long-term maintenance therapy with these agents may be considered for women achieving a good therapeutic response. A low-dose combined oral contraceptive administered cyclically was compared with a GnRH agonist in a randomized trial.[11] Both groups showed overall improvement in dyspareunia, nonmenstrual pain, and dysmenorrhea at 6 months. The rate of recurrent symptoms 6 months after cessation of therapy was equal between groups. Combined oral contraceptives can be administered on a continuous basis if desired. Studies on the efficacy of other formulations of CHCs (vaginal ring and transdermal patch) for treatment of endometriosis pain have not been conducted; however, the use of these agents in endometriosis is reasonable.

Systematic review has concluded that continuous therapy with oral progestins is no more or less effective than other therapies for treatment of endometriosis-associated pain.[12] Two studies of subcutaneous depot medroxyprogesterone revealed statistically equivalent improvement in endometriosis-associated pain compared with the GnRH agonist leuprolide.[13,14] Studies examining the use of the levonorgestrel-releasing intrauterine device (IUD) also suggest efficacy in the treatment of endometriosis-associated pain, and this device is indicated in evidence-based practice guidelines.[9,10,15]

Alternative Drug Treatments

Adolescents (younger than 18 years) experiencing chronic pelvic pain despite therapy with first-line therapies should undergo evaluative laparoscopy prior to initiation of additional pharmacotherapy.[3]

In adolescents with endometriosis diagnosed by laparoscopy or in adults with chronic pelvic pain unresponsive to CHCs or progestins, advanced medical therapy for endometriosis pain may be considered.[3,9,10]

Agents that can be used as advanced medical therapy include danazol and GnRH agonists. Systematic reviews have concluded that both classes are effective choices, and neither class has been proven superior to the other.[16,17] The primary difference between treatments is the side effect profile and available dosage forms; therefore, the choice of agent depends on patient age, preference, and tolerance of side effects. Treatment should be continued for 6 months if relief is obtained.[9,10] For women treated with a GnRH agonist, add-back therapy with an estrogen and progestin combination should be recommended to minimize vasomotor side effects and bone mineral density loss.[9,10,18]

CLINICAL CONTROVERSY

The aromatase inhibitors (specifically anastrazole and letrozole) represent one of the newer classes of drugs being investigated for treatment of endometriosis pain. Although early reports of use are positive, the exact role of these agents remains unknown due to the lack of randomized controlled trials, comparative studies, and concern over long-term side effects such as loss of bone mineral density. Despite these uncertainties, one clinical practice guideline does include letrozole as a therapeutic option. However, the type of patient most (or least) suited for such therapy is unknown at this time.

Although once considered first-line treatment for endometriosis-related pain, nonsteroidal antiinflammatory drugs (NSAIDs) have fallen out of favor because of inconclusive evidence of effectiveness.[9,10] However, NSAIDs may remain an optional, though unproven, treatment for adolescent patients due to concerns over side effects from other non-first-line treatments.[3]

Surgical therapy for endometriosis pain should be performed at the time of diagnosis and again considered for women who do not respond to advanced medical therapy, women with contraindications to medical therapy, and women unable to tolerate side effects caused by medical therapy.[9,10]

Special Populations: Adolescents

4 Treatment goals for endometriosis in adolescent patients are pain control, minimization of disease progression, and preservation of fertility.[3,19] A treatment algorithm that includes therapy for adolescent patients is shown in Figure 90–1. Although progestins are likely to be well tolerated by the adolescent population, clinicians should be aware that efficacy has not been clearly established in this population, and concerns regarding long-term effects on bone mineral density and lipid profile are not clearly defined.[3,20] The effect of drugs on bone mineral density is of particular concern in young women who have not achieved peak bone mass; thus, add-back therapy should be considered for all adolescents receiving GnRH agonist therapy.[3,20] Danazol is not likely to be well tolerated by the adolescent population and generally is not recommended for use.[3,20]

Drug Class Information

When selecting therapy for endometriosis-related pain, the choice of drug within a class often depends on the strength of evidence for efficacy in endometriosis or specific patient factors.

Combined Hormonal Contraceptives CHCs treat the pain of endometriosis by decreasing menstrual flow and regressing endometrial implants through induction of an anovulatory and/or hypoestrogenic state.[3,21] Continuous therapy also can be used to suppress menstruation and induce a "pseudopregnancy"-like state.[3] Evidence-based guidelines consider combined oral contraceptives as effective as other medical therapies for relieving pain from endometriosis.[9,10] No evidence suggests that one combined oral contraceptive is superior to another. Additionally, although no specific studies have examined the efficacy of the contraceptive patch or vaginal ring in endometriosis, the effects of these agents likely are similar to those of the oral formulations.[3] Thus, the choice between CHCs should be guided by patient preference, likelihood of adherence, and cost. Side effects of CHCs typically are mild and may include nausea, bloating, headache, and breakthrough bleeding. However, all CHCs can increase the risk of thromboembolism, so they should not be used in women with a history of thromboembolism or in smokers over age 35 years.

Administration of CHCs may be cyclic (includes a placebo or nondrug week) or continuous. Although no studies have directly compared the two methods, continuous administration is more likely to induce amenorrhea and therefore may be more beneficial in treating dysmenorrhea.[3,20]

Progestins Multiple progestins have been studied for the treatment of endometriosis, and all have demonstrated efficacy for treating related pain.[9,10,12–15] Agents available in the United States include oral medroxyprogesterone, depot medroxyprogesterone (both subcutaneous and intramuscular), megestrol, norethindrone, and the levonorgestrel-releasing IUD. The progestins treat endometriosis via atrophy and decidualization of endometrial tissue. They tend to be less expensive and better tolerated than other advanced medical endometriosis treatments.

Common side effects of systemic progestins include breakthrough bleeding, weight gain, fluid retention, and mood swings. For women desiring immediate future fertility after cessation of therapy, progestins may not be optimal secondary to prolonged amenorrhea and anovulation. Also of concern are unknown long-term effects on bone mineral density associated with these agents. Both depot medroxyprogesterone products carry black box warnings against use for more than 2 years.[22,23] However, in the studies that directly compared the subcutaneous form of depot medroxyprogesterone to leuprolide over a treatment period of 6 months, the extent and degree of bone loss were less severe with the progestin.[13,14] Specific progestin dosing information is given in Table 90–1.

Gonadotropin-Releasing Hormone Agonists GnRH agonists create a functional oophorectomy via inhibition of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion. This, in turn, diminishes endometrial implants. When first initiated, GnRH agonists create an initial gonadotropin flare prior to receptor downregulation that may cause a temporary increase in pain. Initiating therapy during the midluteal phase may minimize such effects.

Therapy with a GnRH agonist is superior to placebo and comparable to danazol for relief of endometriosis-associated pain.[16] Response rates are ~85% to 100% after 6 months of therapy, but recurrence rates at 5 years are 53%.[16,24–26] Although a GnRH agonist typically is taken for 6 months, one comparative study has shown equivalent efficacy and recurrence rates between 3 and 6 months of GnRH agonist therapy, and evidence-based guidelines therefore recommend 3 months of therapy as an option.[9,10,27] Therapy may also be extended beyond 6 months to maintain efficacy, although data regarding such extended usage are limited.

The three GnRH agonists currently available in the United States are goserelin, leuprolide, and nafarelin. These agents differ primarily by route of administration; therefore, the choice of therapy depends on patient preference. Specific dosing information for the GnRH agonists is given in Table 90–1.

Side effects are the primary limitation of GnRH agonist use. The pharmacologically induced hypoestrogenic environment results in bone loss and vasomotor symptoms such as hot flashes, vaginal dryness, and insomnia. Loss of bone mineral density is estimated at 4% to 6% over 6 months of GnRH agonist therapy and occurs at both the hip and spine, but this loss is partially to fully recoverable upon cessation of the drug.[28] Bone loss is progressive as use of the drugs is extended beyond 6 months; whether reversibility is maintained after such longer treatment periods is unknown.[29] Add-back therapy with estrogen and progestin combinations has been proven effective for treatment of vasomotor symptoms and

TABLE 90-1 Pharmacologic Therapy For Endometriosis-Associated Pain

Drug	Dose	Comments
CHCs		
Combined oral contraceptives (various)	One orally daily	Continuous administration may lessen dysmenorrhea Contraindicated in women with a history of thromboembolism; avoid in women older than 35 years who smoke
Contraceptive patch (Ortho-Evra)	One patch weekly	Continuous administration may lessen dysmenorrhea Contraceptive efficacy may be diminished in women >90 kg (198 lbs) Contraindicated in women with a history of thromboembolism; avoid in women older than 35 years who smoke
Contraceptive vaginal ring (Nuva Ring)	One ring monthly	Continuous administration may lessen dysmenorrhea Contraindicated in women with a history of thromboembolism; avoid in women older than 35 years who smoke
Progestins		
MPA	150 mg IM every 3 months 120 mg sub-Q every 3 months	Generally well tolerated and less costly than GnRH-a or danazol Black box warning to limit therapy to no more than 2 years' duration May delay return of fertility
LNG-IUS	One system inserted for up to 5 years	Additional benefit is long-term contraception May be difficult to insert in nulliparous women
GnRH-a		
Leuprolide	11.25 mg IM every 3 months	Vasomotor symptoms and bone loss may limit use Add-back therapy improves side effects and reduces bone loss Not preferred in younger adolescent patients secondary to bone loss
Goserelin	3.6 mg sub-Q monthly	Vasomotor symptoms and bone loss may limit use Add-back therapy improves side effects and reduces bone loss Not preferred in younger adolescent patients secondary to bone loss
Nafarelin	200 mcg (one spray) intranasally twice daily	Vasomotor symptoms and bone loss may limit use Add-back therapy improves side effects and reduces bone loss Not preferred in younger adolescent patients secondary to bone loss
Other		
Danazol	600–800 mg orally daily in divided doses	Androgenic side effects limit use; not preferred in adolescent patients secondary to side effect profile
NSAIDs		
Ibuprofen	400 mg orally every 4–6 hours	Use with caution in women with reactive airways disease, renal disease, or history of GI ulcer
Naproxen	250 mg orally every 6–8 hours	Use with caution in women with reactive airways disease, renal disease, or history of GI ulcer
Aromatase inhibitors		
Anastrazole	1 mg orally daily	Unknown efficacy compared with other therapies Add-back therapy may be necessary to prevent bone loss Reserve for failures to other therapeutic options
Letrozole	2.5 mg orally daily	Unknown efficacy compared with other therapies Add-back therapy may be necessary to prevent bone loss Reserve for failures to other therapeutic options

CHCs = combined hormonal contraceptives, GI = gastrointestinal, GnRH-a = gonadotropin-releasing hormone agonists, IM = intramuscular, LNG-IUS = levonorgestrel intrauterine system, MPA = medroxyprogesterone acetate, NSAIDs = nonsteroidal antiinflammatory drugs, sub-Q = subcutaneous

prevention of bone loss while maintaining GnRH agonist efficacy.[18] Add-back therapy dosing should approximate the low doses used for hormone replacement therapy. Thus, CHCs should not be prescribed for this purpose.

Women receiving GnRH agonist therapy should be encouraged to take supplemental calcium and to exercise. One small study suggests that women who exercise (walking and aerobic sessions) during 6 months of GnRH agonist therapy sustain similar bone mineral loss during therapy but have better recovery of bone mineral density after cessation of therapy compared with women who do not exercise.[30]

Danazol Danazol is a synthetic steroid analogue of 17-ethinyl testosterone. It induces anovulation, amenorrhea, and endometrial atrophy through pituitary suppression of the midcycle LH and FSH surge and induction of a high-androgen, low-estrogen environment. The drug also has immunosuppressive activity that may contribute to its efficacy. Formerly the "gold standard" of endometriosis treatment, the popularity of danazol has decreased with the development of agents with more favorable side effect profiles.

Danazol has proven effective as empirical as well as postoperative therapy. Symptomatic improvement has been reported in up to 80% to 90% of women using the drug, with the best results seen in women achieving amenorrhea.[31] A systematic review concluded that 6 months of danazol therapy is superior to placebo in relieving painful symptoms.[17]

The primary limitation of danazol therapy is the high occurrence of androgenic side effects, including weight gain, acne, hot flashes, decreased breast size, hirsutism, and increased low-density lipoprotein cholesterol. Use of vaginal danazol (200 mg/day) has been investigated in one small study, and this route of administration was effective in treatment of endometriosis pain while minimizing systemic side effects.[32] However, more data are needed before this strategy can be routinely recommended.

Danazol should not be initiated in women with hyperlipidemia or liver disease. Danazol is teratogenic, and barrier forms of contraception must be used. The dose of danazol ranges from 200 to 800 mg/day; most studies have used doses of 600 to 800 mg. Specific dosing information is given in Table 90–1.

Nonsteroidal Antiinflammatory Drugs NSAIDs are thought to treat the painful symptoms of endometriosis by interfering with prostaglandin production, but data are lacking to indicate the efficacy of this class of medications specifically in patients with

endometriosis.[9,10] Long-term use of these agents may be limited by gastrointestinal or renal toxicity. They also may aggravate reactive airway disease and should be used with caution in such patients. Despite this uncertain risk-to-benefit ratio, some clinicians may still wish to try NSAIDs in patients unable to take other endometriosis therapies. NSAIDs commonly used for treatment of gynecologic pain are ibuprofen and naproxen.[31] Specific dosing information is listed in Table 90–1.

Aromatase Inhibitors Aromatase is a key enzyme in the biosynthesis of estrogen, and elevated levels of aromatase have been found in endometrial lesions compared with normal endometrium.[6,33] Thus, aromatase inhibitors are thought to treat endometriosis pain by direct inhibition of estrogen production. Data on efficacy of aromatase inhibitors in treating endometriosis pain are largely limited to case reports and nonrandomized, noncomparative studies, but there is evidence of efficacy for both letrozole and anastrazole, alone and in combination with GnRH agonists.[33]

Most information about the side effects of aromatase inhibitors comes from data in postmenopausal women. These side effects include hot flashes, vaginal dryness, and loss of bone mineral density. They have been minimized in the endometriosis population by use of add-back therapy.[6,33] Specific dosing information is listed in Table 90–1.

PHARMACOECONOMIC CONSIDERATIONS

6 Several cost considerations must be made when choosing endometriosis therapy. The cost of medical therapy must be weighed against the cost of surgical therapy, and the costs of each type of medical therapy must be weighed against another. Unfortunately, no recent data exist that explore the cost-effectiveness of the various treatment options. Generally, GnRH agonists and aromatase inhibitors are the most expensive agents, and CHCs and progestins are the least expensive.

EVALUATION OF THERAPEUTIC OUTCOMES

4 Monitoring of endometriosis therapy is focused on subjective relief of symptoms.[31] Although objective confirmation of lesion regression by laparotomy is feasible, the results typically are misleading because the number and size of lesions do not correlate well with symptoms.[31]

Endometriosis-related pain should be relieved within 2 months of initiating medical therapy. If symptoms persist, consideration should be given to different medical and/or surgical therapy. For endometriosis-related infertility, most experts recommend 6 months of watchful waiting after surgical intervention. If pregnancy is not achieved within that time, assisted reproductive techniques can be considered.

Careful monitoring of the patient for side effects to recommended drug therapy is important. Most of the monitoring can be accomplished by eliciting any subjective complaints from the patient at routine follow-up visits. However, certain drug therapies may require additional objective monitoring, such as fasting lipid profile and blood pressure measurements. The role of routine bone mineral density testing as a monitoring parameter for patients receiving GnRH agonists or aromatase inhibitors is not yet determined, especially because accuracy of bone mineral density results in predicting fracture risk in younger patients has not been well established, nor has a threshold of loss been established for discontinuation of therapy.

ABBREVIATIONS

CHCs: Combined hormonal contraceptives

FSH: Follicle-stimulating hormone

GnRH: Gonadotropin-releasing hormone

GnRH-a: Gonadotropin-releasing hormone agonist

IUD: Intrauterine device

LH: Luteinizing hormone

LNG-IUS: Levonorgestrel-releasing intrauterine system

NSAIDs: Nonsteroidal antiinflammatory drugs

Nulliparous: having never been pregnant

CHAPTER 91

Hormone Therapy in Women

SOPHIA N. KALANTARIDOU, DEVRA K. DANG, SUSAN R. DAVIS, AND KARIM ANTON CALIS

KEY CONCEPTS

1. The decision to use menopausal hormone therapy must be individualized and based on several parameters, including symptoms, osteoporosis risk, cardiovascular disease risk, breast cancer risk, and thromboembolism risk.
2. The lowest effective dose of hormone therapy for the shortest duration needed for effective symptom control should be prescribed, weighing the potential benefits and risks for the individual woman.
3. Hormone therapy is the most effective treatment option for alleviating vasomotor and vaginal symptoms of menopause.
4. Osteoporosis prevention remains an indicated use of estrogen products; however, nonestrogen products, specifically bisphosphonates, are as effective as hormone therapy for preventing osteoporosis.
5. Hormone therapy improves depressive symptoms in symptomatic menopausal women, most likely by relieving flushing and improving sleep. However, it may worsen quality of life in women without hot flushes.
6. Cardiovascular disease, including coronary artery disease, stroke, and peripheral vascular disease, is the leading cause of death among women. Postmenopausal hormone therapy should not be used for reducing the risk of cardiovascular disease.
7. Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (unopposed estrogen), hormone therapy in women who have not undergone hysterectomy should include a progestogen in addition to the estrogen.
8. Use of hormone therapy at doses lower than those prescribed historically is effective in the management of menopausal symptoms.
9. Results from randomized trials of hormone therapy in postmenopausal women cannot be extrapolated to premenopausal women with ovarian dysfunction. Women with primary ovarian insufficiency need exogenous sex steroids to compensate for decreased production by their ovaries.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

MENOPAUSE AND PERIMENOPAUSAL AND POSTMENOPAUSAL HORMONE THERAPY

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity.[1] By definition, it is a physiologic event that occurs after 12 consecutive months of amenorrhea, so the time of the final menses is determined retrospectively. Women who have undergone hysterectomy must rely on their symptoms to estimate the actual time of menopause.

EPIDEMIOLOGY

The median age at the onset of menopause in the United States is 51 years, whereas the average life expectancy for women is 81 years. Thus, American women can expect to be postmenopausal for more than one third of their lives. As the U.S. population ages, the number of women experiencing menopause is expected to rise. Although the age at menarche has declined steadily over centuries, probably as a result of improved nutrition, the age of onset for menopause appears to be relatively stable. Cigarette smokers, however, experience menopause 2 years earlier than nonsmokers on average. Women who have undergone hysterectomy are also more likely to have an earlier menopause despite preservation of their ovaries.

ETIOLOGY

Menopause refers to loss of ovarian function and subsequent hormonal deficiency. This can be due to the normal process of aging (i.e., natural menopause), surgery (total abdominal hysterectomy, bilateral oophorectomy), medications (e.g., chemotherapy), or pelvic irradiation.

PATHOPHYSIOLOGY

Characteristics of the human menstrual cycle throughout reproductive life are well described.[2] A woman is born with approximately two million primordial follicles in her ovaries. During a normal reproductive life span, she ovulates fewer than 500 times. The vast majority of follicles undergo atresia.

The hypothalamic–pituitary–ovarian axis dynamically controls reproductive physiology throughout the reproductive years. The pituitary is regulated by pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH), produced by the pituitary in response to GnRH, regulate ovarian function. These gonadotropins also are influenced by negative feedback from estradiol and progesterone. Ovarian follicular activity is reflected by the circulating concentrations of sex steroids and by peptide hormones (e.g., inhibin and activin). The sex steroids include estradiol,

produced by the dominant follicle; progesterone, produced by the corpus luteum after maturation of the dominant ovarian follicle; and androgens, primarily testosterone and androstenedione, secreted by the ovarian stroma. Sex steroids are important for the healthy functioning of many organs, including the bones, brain, skin, and reproductive and urogenital tracts. They act primarily by regulating gene expression.

Pathophysiologic changes associated with menopause are caused by loss of ovarian follicular activity.[1] Ovarian primordial follicle numbers decrease with advancing age, and at the time of the menopause, few follicles remain in the ovary. Hence, the postmenopausal ovary is no longer the primary site of estradiol or progesterone synthesis. The postmenopausal ovary secretes primarily androstenedione and testosterone. In contrast to the acute fall in circulating estrogen at the time of menopause, the decline in circulating androgens commences in the decade leading up to the average age of natural menopause and closely parallels increasing age.[3] Androgens are secreted by both the ovaries and the adrenal glands. Following menopause, direct ovarian androgen secretion appears to account for as much as 50% of testosterone production, with the adrenal gland being a less important source. Hypertrophy of the ovarian stroma may develop after menopause, probably secondary to high LH concentrations, thereby resulting in increased ovarian testosterone production. Alternatively, the ovaries may become fibrotic and a poor source of sex steroids.

No endocrine event clearly signals the time just prior to final menses.[4] Nonetheless, as women age, a progressive rise in circulating FSH[5] and a concomitant decline in ovarian inhibin[4] are observed. In women who continue to experience menstrual bleeding, FSH determinations on day 2 or 3 of the menstrual cycle are considered elevated when concentrations exceed 10 to 12 milli international units/mL (10 to 12 IU/L), an indication of diminished ovarian reserve. Clear elevations in serum FSH are seen in women approximately at age 40 years.[4] When ovarian function has ceased, serum FSH concentrations are greater than 40 milliinternational units/mL (40 IU/L).

CLINICAL PRESENTATION

The perimenopause is the period immediately prior to the menopause and the first year after menopause. The menopausal transition is the period of time when the endocrinologic, biologic, and clinical features of the approaching menopause commence.[4] The menopausal transition usually begins approximately 4 years prior to menopause and is characterized by menstrual cycle irregularity caused by increased frequency of anovulatory cycles. Vasomotor symptoms (hot flushes and night sweats), psychological symptoms (anxiety, mood swings, and depression), and disturbances of sexuality are increased markedly in the perimenopause. Menopause is characterized by a 10- to 15-fold increase in circulating FSH concentrations compared with concentrations of FSH in the follicular phase of the cycle, a fourfold to fivefold increase in LH, and a greater than 90% decrease in circulating estradiol concentrations.[4] During the perimenopause, FSH concentrations may rise to the postmenopausal range during some cycles but return to premenopausal levels during subsequent cycles. Thus, high concentrations of FSH should not be used to diagnose menopause in perimenopausal women. However, vasomotor symptoms in perimenopausal women may require treatment despite the presence of menstrual bleeding. Abnormal thyroid function and other conditions that may cause similar symptomatology should be excluded first. Dysfunctional uterine bleeding may occur during the perimenopausal years because of anovulatory cycles, but other gynecologic causes also should be considered. Treatment options for dysfunctional uterine bleeding include progestogens or low-dose oral contraceptives.

CLINICAL PRESENTATION AND DIAGNOSIS OF PERIMENOPAUSE AND MENOPAUSE

Symptoms

- Vasomotor symptoms (hot flushes and night sweats)
- Sleep disturbances
- Mood changes
- Sexual dysfunction
- Problems with concentration and memory
- Vaginal dryness and dyspareunia
- Arthralgia

Signs

- Perimenopause: Dysfunctional uterine bleeding as a result of anovulatory cycles (other gynecologic disorders should be excluded)
- Menopause: Signs of urogenital atrophy

Laboratory Tests

- Perimenopause: FSH on day 2 or 3 of the menstrual cycle greater than 10–12 milliinternational units/mL (10–12 IU/L)
- Menopause: FSH greater than 40 milliinternational units/mL (40 IU/L)

Other Relevant Diagnostic Tests

- Thyroid function tests
- Iron stores

TREATMENT

Treatment options for menopause include nonpharmacologic therapy for mild symptoms, and hormonal or nonhormonal therapy for moderate to severe symptoms.

DESIRED OUTCOMES

Menopause is a natural life event, not a disease. The goals of therapy for menopause are to relieve symptoms and improve quality of life while minimizing adverse effects.

GENERAL APPROACH TO TREATMENT

In women with mild vasomotor and/or vaginal symptoms, nonpharmacologic therapy can be considered. However, many women will require pharmacologic therapy for more severe symptoms. Figure 91–1 outlines a treatment algorithm for women requiring pharmacologic therapy. In the absence of contraindications, hormone therapy is appropriate mainly for women with hot flushes and vulvar or vaginal atrophy.[6] It is contraindicated in women with endometrial cancer, breast cancer, undiagnosed vaginal bleeding, coronary heart disease, thromboembolism (including recent spontaneous thrombosis or in the presence of a thrombophilia), stroke or transient ischemic attack, and active liver disease.[6] Relative contraindications include uterine leiomyoma, migraine headaches, and seizure disorder. In addition, oral estrogen should be avoided in women with hypertriglyceridemia, liver disease, and gallbladder disease. For these women, transdermal administration is a safer approach. The main reasons for discontinuing hormone therapy are side effects such as bleeding, breast tenderness, bloating, and "premenstrual-like symptoms." Reducing the dose or changing the regimen or the route of administration can minimize these effects.

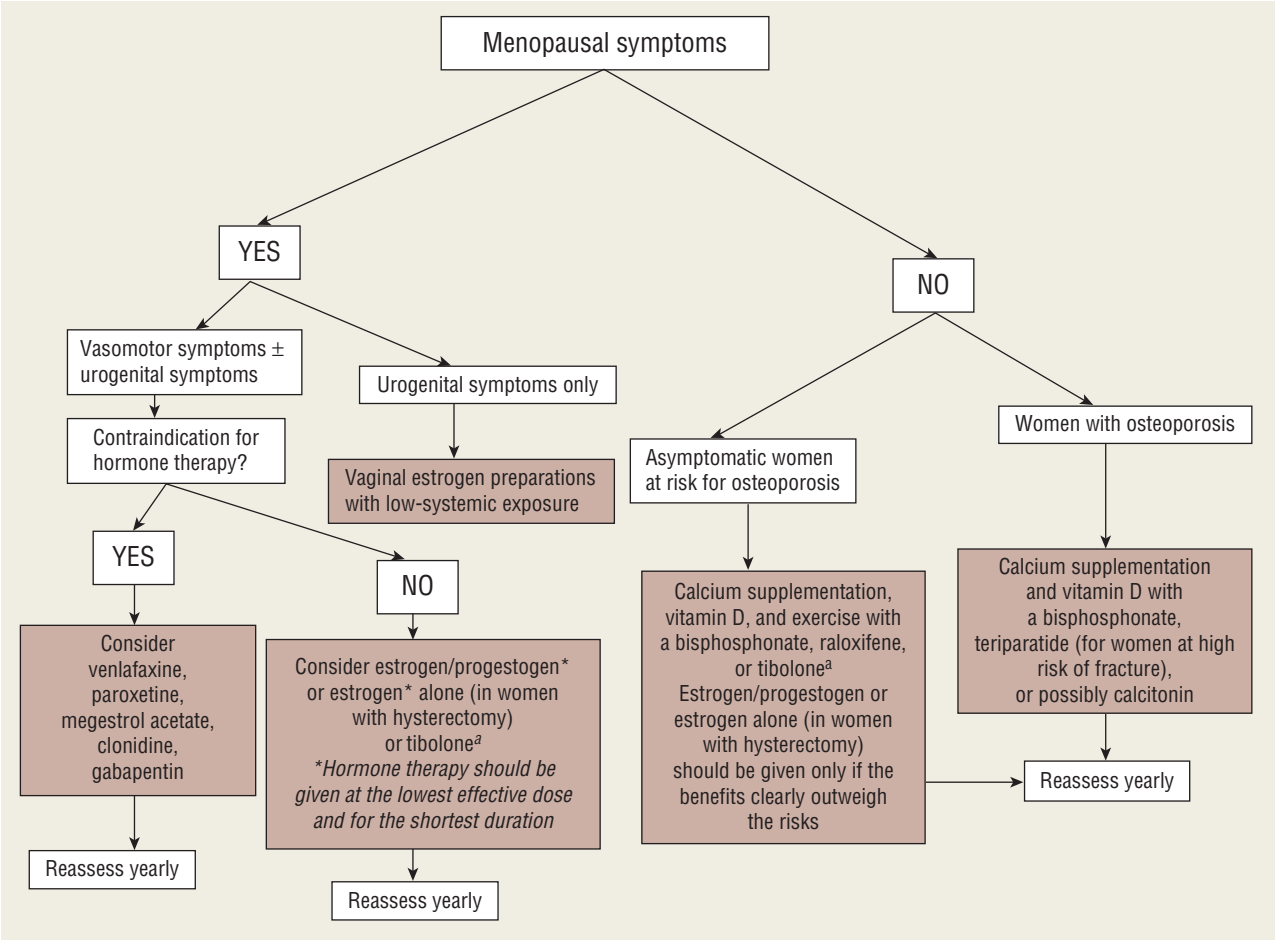

FIGURE 91-1. Algorithm for pharmacologic management of menopause symptoms. [a]Tibolone is currently not approved for use in the United States.

1 The decision to use hormone therapy must be individualized and based on several parameters, including menopausal symptoms, osteoporosis risk, cardiovascular disease risk, breast cancer risk, and thromboembolism risk.

2 Clinicians should prescribe the lowest effective dose of hormone therapy for the shortest duration needed for effective symptom control, weighing the potential benefits and risks for the individual woman. Recommendations should be specific to each woman's clinical profile and concerns. Approved indications of hormone therapy include treatment of vasomotor symptoms and urogenital atrophy and prevention of osteoporosis. Weighing risks and benefits, the Food and Drug Administration (FDA) determined that the indication for vasomotor symptoms (hot flushes and night sweats) should remain unchanged, but the other two indications for hormone therapy should be revised. For treatment of vasomotor symptoms, systemic hormone therapy remains the most effective pharmacologic intervention (see Fig. 91–1). For symptoms of urogenital atrophy, such as vaginal dryness, intravaginal products should be considered. In addition, although prevention of postmenopausal osteoporosis remains an indicated use of hormone therapy, consideration should be given to approved nonestrogen products, such as raloxifene and bisphosphonates (see Fig. 91–1).

Prior to initiating pharmacologic therapy, a complete medical history and physical examination should be performed. Medical history should include a personal or family history of cardiovascular disease and thrombotic problems. The physical examination should include a complete cardiovascular examination, clinical assessment of thyroid status, and breast and pelvic examinations. Papanicolaou cervical cytologic examination and screening mammography negative for malignancy are required before initiating hormone therapy. Thyroid function tests and lipoprotein lipid profile also are performed at the discretion of the clinician.

Each patient should be evaluated for the presence of indications (i.e., menopausal symptoms such as hot flushes or vaginal dryness) and possible contraindications. A thorough discussion of the risks and benefits of hormone therapy should be completed with the patient so that she can weigh the risks and benefits versus alternatives and make a rational decision about whether to use hormone therapy.

NONPHARMACOLOGIC THERAPY

In some women, menopausal symptoms can be managed effectively with lifestyle modifications, including wearing layered clothing that can be removed or added as necessary, lowering room temperature, decreasing intake of hot spicy foods, caffeine, and hot beverages, exercise, and other good general health practices. More recently, dietary supplements and nonpharmacologic therapies have been promoted as "complementary medicine" alternatives to hormone therapy. To date, little evidence supports the use of such nonprescription herbal products, which include various herbal remedies and soy-based supplements.

PHARMACOLOGIC THERAPY

Pharmacologic therapy is the mainstay of management of menopausal symptoms and includes both hormonal (estrogen +/– progestogen) and nonhormonal medications. In the past, hormone therapy has also been used for the prevention of chronic medical conditions (e.g., cardiovascular disease) thought to be associated with loss of female hormones, and estrogen and progestogen therapy for menopause was termed hormone replacement therapy. However, publication of the results of the landmark Women's Health Initiative study in 2002 shifted the focus toward using estrogen and progestogen at the lowest (instead of replacement) doses needed for the relief of menopausal symptoms only.

Published Guidelines

A number of national and international guidelines and consensus statements on the management of menopause are available. These include position statements from the North American Menopause Society, the Endocrine Society, the American Association of Clinical Endocrinologists, the Society of Obstetricians and Gynaecologists of Canada, the International Menopause Society, and the National Institutes of Health.[7–14] The United States Preventive Services Task Force also provides a recommendation statement on the use of hormone therapy for the prevention of chronic medical conditions in postemenopausal women.[15] The most current guidelines should be consulted, as menopause is a major area in women's health with new data being published continuously.

DRUG TREATMENT OF FIRST CHOICE

3 Hormone therapy is the most effective treatment option for alleviating vasomotor and vaginal symptoms. In women with an intact uterus, hormone therapy consists of an estrogen plus a progestogen. In women who have undergone hysterectomy, estrogen therapy is given unopposed by a progestogen.

Hormone Therapy

Approved indications of postmenopausal hormone therapy include treatment of menopausal symptoms (e.g., hot flushes, night sweats, and urogenital atrophy) and osteoporosis prevention.[16] Much of what is known about the benefits and risks of hormone therapy in postmenopausal women comes from the landmark Women's Health Initiative (WHI) study. The WHI randomized controlled trial was a chronic disease prevention trial designed to evaluate the role of hormone therapy in reducing the risks of cardiovascular disease in older women and at the same time to investigate the effects on the risk of breast cancer.[17,18] The trial was conducted in a total of 68,132 mainly asymptomatic women who were an average 12 to 13 years postmenopausal (mean age 63 ± 7.11 years).[17,18] The continuous combined oral estrogen plus progestogen arm (conjugated equine estrogens 0.625 mg/day plus medroxyprogesterone acetate 2.5 mg/day) of the WHI trial was terminated early. This arm included 16,608 relatively healthy postmenopausal women aged 50 to 79 years at enrollment (mean age 63.2 years). The primary outcome was coronary heart disease (CHD) events, defined as nonfatal myocardial infarction and coronary artery disease death, with invasive breast cancer as the primary adverse outcome. The study also examined secondary outcomes, including stroke, thromboembolic disease, fractures, colon cancer, and endometrial cancer.[17] After a mean follow-up of 5.2 years (planned duration 8.5 years), the Data and Safety Monitoring Board recommended stopping this arm of the trial because of the occurrence of a prespecified level of invasive breast cancer. That is, women who received the active drug had an increased risk of invasive breast cancer (hazard ratio [HR] 1.26, 95% confidence interval [CI] 1–1.59), and the overall risks exceeded benefits.[17] The study also found increased CHD events (HR 1.29, 95% CI 1.02–1.63), stroke (HR 1.41, 95% CI 1.07–1.85), and pulmonary embolism (HR 2.13, 95% CI 1.39–3.25). Beneficial effects included decreases in hip fracture (HR 0.66, 95% CI 0.45–0.98) and colorectal cancer (HR 0.63, 95% CI 0.43–0.92).[17] Results from this study indicated that short-term use (less than 1 year) has risks for CHD and thromboembolic disease events. The number of deaths was similar among the groups.

After a mean follow-up of 7 years, the Data and Safety Monitoring Board also recommended stopping the oral estrogen-alone arm of the study. This arm consisted of 10,739 women who had undergone hysterectomy. Estrogen-only therapy had no effect on coronary heart disease risk and was not associated with increased breast cancer risk but increased stroke risk (HR 1.39, [95% CI 1.1–1.77]) and decreased hip fracture risk (HR 0.61, 95% CI 0.41–0.91]).[18]

Among women in the estrogen plus progestogen arm, one serious adverse event occurred in every 100 women treated for 5 years. Specifically, the study suggested that for every 10,000 women taking combined hormone therapy, there would be eight more cases of breast cancer, seven more cases of CHD, eight more cases of stroke, and eight more cases of pulmonary embolism per year. However, six fewer colorectal cancers and five fewer hip fractures would be expected.[17,19] For the majority of women who had never used hormone therapy before enrolling in the study (6,280 treated with estrogen plus progestogen and 6,024 treated with placebo), the HR for breast cancer was 1.06 (95% CI 0.81–1.38), indicating that the burden of risk for breast cancer resulted from use of hormone therapy for more than 5 years. Subsequently, a large epidemiologic study reported a greater risk estimate of breast cancer for combined estrogen plus progestogen use as well as increased risk for estrogen-only therapy.[19] However, interpretation of these findings is limited by selection bias because the risk profiles of women who used hormone therapy were significantly different from those of nonusers.[19] It is unclear whether the type of estrogen compound or the dose, route, or administration method could be at least partly responsible for the risks observed in the WHI trial.

Regulatory authorities expressed major concerns about hormone therapy use following the publication of the results of the WHI trial,[16,20] and many women either stopped or become reluctant to use hormone therapy.[21] The WHI trial was conducted in older postmenopausal women. No randomized controlled clinical trials of the population of women normally targeted for hormone therapy (i.e., symptomatic perimenopausal or early postmenopausal women) have been reported. Although hormone therapy is not indicated for prevention of chronic diseases of aging, it remains the most effective treatment for vasomotor symptoms, impaired sleep quality, and urogenital symptoms of menopause.

Although it has been proposed that hormone therapy should be prescribed at the lowest possible dose for the shortest possible time,[16] evidence that new low-dose regimens are safer than traditionally prescribed doses is lacking. Weighing the risks and benefits, the FDA mandated the addition of new safety warnings to the labels of all systemic estrogens (regardless of route or dosage form), including estrogen-only and combined estrogen–progestogen products.[20] The labels caution that use of estrogen-containing hormone therapy regimens by postmenopausal women may be associated with an increased risk of myocardial infarction, stroke, breast cancer, and thromboembolism.[20]

Benefits of Hormone Therapy

Hormone therapy has been shown to relieve vasomotor symptoms, vaginal atrophy, prevent and treat osteoporosis, and reduce the risk of colon cancer.

Vasomotor Symptoms The major indication for postmenopausal hormone therapy is management of vasomotor symptoms. Most women with vasomotor symptoms require hormone treatment for fewer than 5 years, so the risks of therapy appear to be small.

Fewer than 25% of women experience a menopausal transition without symptoms, whereas more than 25% suffer severe menopausal symptoms, most commonly hot flushes and night sweats.[22]

Without treatment, hot flushes in most women typically disappear within 1 to 2 years, but in some untreated women hot flushes continue for more than 20 years.[23] Women with mild vasomotor symptoms often experience relief by lifestyle modification and at least 25% of women in clinical trials reported significant improvement of vasomotor symptoms when taking placebo. However, no therapy has been shown to be as effective as estrogen therapy in alleviating significant vasomotor symptoms. Estrogens diminish hot flushes in most women, and all types and routes of administration of estrogen are equally effective.[24] A dose-dependent relationship between estrogen administration and suppression of hot flushes is well established. Some women, especially younger women, may require a higher than average dose of estrogen to suppress symptoms. On the other hand, many women with hot flushes at the time of menopause require lower doses of estrogen.[24] Hormone therapy for menopausal symptoms can be stopped about 2 or 3 years after starting. If treatment can be tapered and stopped within 5 years, no evidence of increased risk of breast cancer is seen.[17]

Vaginal Atrophy Estrogen receptors have been demonstrated in the lower genitourinary tract, and at least 50% of postmenopausal women suffer symptoms of urogenital atrophy caused by estrogen deficiency.[25] Atrophy of the vaginal mucosa results in vaginal dryness and dyspareunia. Lower urinary tract symptoms include urethritis, recurrent urinary tract infection, urinary urgency, and frequency. Most women with significant vaginal dryness because of vaginal atrophy require local or systemic estrogen therapy for symptom relief. Such treatment also reduces the risk of recurrent urinary tract infections, possibly by modifying the vaginal flora.[26] Vaginal dryness and dyspareunia can be treated with an intravaginal estrogen cream, tablet, or ring. In clinical trials, vaginal estrogen appears to be better than systemic estrogen for relieving these symptoms and avoids high levels of circulating estrogen. Concomitant progestogen therapy generally is unnecessary if women are using low-dose micronized 17β-estradiol. However, regular use of conjugated equine estrogens (CEE) vaginal creams and other products that potentially promote endometrial proliferation in women with an intact uterus requires intermittent progestogen challenges (i.e., for 10 days every 12 weeks). This is an important caveat because vaginal atrophy requires long-term estrogen treatment.[26]

Urinary incontinence, which becomes more prevalent with increasing age, usually is not improved by estrogen therapy. In one large clinical trial, estrogen–progestogen therapy actually increased incontinence.[27]

Osteoporosis Prevention and Treatment Therapy directed at menopausal symptoms, such as hot flushes, often is short term. However, therapy directed at prevention of osteoporosis should be long term. For osteoporosis prevention, the advantages of hormone therapy must be weighed against the risks, including thrombosis and the increased incidence of cardiovascular disease and breast cancer;[17] and consideration should be given to approved nonestrogen alternatives.

Postmenopausal osteoporosis is a serious age-related disease that affects millions of women throughout the world. Menopause is accompanied by accelerated bone loss, and the central role of estrogen deficiency in postmenopausal osteoporosis is well established. Osteoporosis is characterized by reduced bone mass associated with architectural deterioration of the skeleton and increased risk for fracture.[8] Estrogen deficiency results in bone loss through its actions in accelerating bone turnover and uncoupling bone formation from resorption. It is important to recognize that bone loss commences 2 years before the final menstrual period.[28] Throughout menopause, the average loss of bone mineral density (BMD) is around 6.4% at the lumbar spine and 4%–5% at the femoral neck, with obese women experiencing less bone loss than nonobese women.[28] Annual bone mass decreases of 0.5% to 1% are seen after age 65 years.[29] An observational study of more than 9,000 postmenopausal women examined the relationship between endogenous estrogens and BMD, bone loss, fractures, and breast cancer.[30–33] Women with detectable serum estradiol concentrations (5–25 pg/mL [18–92 pmol/L]) had a 6% to 7% higher BMD at the total hip and spine compared with women with undetectable levels (less than 5 pg/mL [18 pmol/L]).[32] They also had significantly less bone loss at the hip than women with undetectable levels.[31] Women with undetectable serum estradiol concentrations had a relative risk of 2.5 for subsequent hip and vertebral fractures.[33] However, women with the highest estradiol serum concentrations had the greatest risk of developing breast cancer.[30]

The WHI randomized trial was the first study to demonstrate that hormone therapy reduces the risk of fractures at the hip, spine, and wrist in women not selected for having osteoporosis.[17,34] Hip and clinical vertebral fractures are reduced by 34%, and total osteoporotic fractures are reduced by 24%.[34] These findings are in agreement with observational data and several meta-analyses of the efficacy of hormone therapy for reducing fractures in postmenopausal women.[35] Estrogen therapy reduces bone turnover and increases bone density in postmenopausal women of all ages. The protective effect persists as long as the treatment is maintained. With cessation of therapy, postmenopausal bone loss resumes at the same rate as in untreated women. The standard bone-sparing daily estrogen dose is equivalent to 0.625 mg CEE.[36] However, lower doses of estrogen have been shown to increase bone mass to the same extent as standard-dose estrogen therapy.[37]

4 Osteoporosis *prevention* remains an indicated use of estrogen products; however, nonestrogen products, specifically bisphosphonates, are as effective as hormone therapy for preventing osteoporosis. The FDA has withdrawn the "osteoporosis *treatment*" indication from estrogen products. Long-term hormone therapy is no longer an appropriate first-choice option for osteoporosis prevention because of the risks associated with its long-term use. Therefore, hormone therapy should be considered for osteoporosis prevention only in women at significant risk for osteoporosis who cannot take nonestrogen treatments such as bisphosphonates.

Bisphosphonates are analogs of pyrophosphate that inhibit bone resorption. Drugs in this class with FDA-approved indications for osteoporosis include alendronate, risedronate, ibandronate, and zoledronic acid. Bisphosphonates reduce the risk of both hip and vertebral fractures by 30% to 50%.[8] Bisphosphonates have no known impact on the incidence of cardiovascular disease or breast or endometrial cancer. A few trials have shown improved bone density over single therapy when a bisphosphonate is combined with estrogen or the selective estrogen receptor modulator raloxifene, but no fracture data are available as of this writing.[38] Some experts recommend cessation of bisphosphonate therapy after 5–10 years use because of accumulation in bone.[39]

General protective measures, such as regular weight-bearing exercise and avoidance of detrimental lifestyle habits such as smoking and alcohol abuse, are appropriate for all women. Some women require calcium supplementation to their dietary intake. Adequate vitamin D intake and/or supplementation is also needed. See Chap. 99 for a full discussion of osteoporosis prevention and treatment.

Colon Cancer Risk Reduction

Colorectal cancer is the fourth most common cancer and the second leading cause of cancer death in the United States (see Chap. 138). The estrogen–progestogen arm of the WHI study was the first randomized controlled trial to confirm that combined estrogen–progestogen therapy reduces colon cancer risk. Compared with placebo, six fewer colorectal cancers are reported per year in every 10,000 women taking hormone therapy.[17]

Quality of Life, Mood, Cognition, and Dementia

5 Hormone therapy improves depressive symptoms in symptomatic menopausal women, most probably by relieving flushing and improving sleep.[40] Women with vasomotor symptoms receiving hormone therapy have improved mental health and fewer depressive symptoms compared with women receiving placebo; however, hormone therapy may worsen quality of life in women without flushes.[41]

There is no evidence that hormone therapy improves quality of life or cognition in older, asymptomatic women.[40–44]

More than 33% of women 65 years and older will develop dementia during their lifetime.[45] Several observational studies have suggested that estrogen therapy may be protective against Alzheimer disease (see Chap. 63). The WHI Memory Study (an ancillary study of WHI trial) evaluated the effect of combined hormone therapy on dementia and cognition in 4,532 women 65 to 79 years old.[43] The study found that postmenopausal women 65 years and older taking estrogen plus progestogen therapy had twice the rate of dementia, including Alzheimer disease, than women taking placebo (HR 2.05, 95% CI 1.21–3.48).[43] In addition, estrogen plus progestogen therapy in these women did not prevent mild cognitive impairment, a cognitive and functional state between normal aging and dementia that frequently progresses to dementia.[43] The estrogen alone arm of the WHI trial showed similar findings.[46,47]

Hormone therapy does not improve quality of life in postmenopausal women who do not have vasomotor symptoms. Hormone therapy does not improve cognitive function compared with placebo and, more importantly, produces an increased risk (albeit small) of clinically meaningful cognitive decline among women 65 years and older taking hormone therapy.[41–44,46,47]

CLINICAL CONTROVERSY

Some clinicians believe that hormone therapy improves well-being and quality of life of postmenopausal women, whereas others believe that hormone therapy, at best, has no effect. Hormone therapy improves mood and well-being mainly in women with vasomotor symptoms and sleep disturbance.

Other Effects

Diabetes In healthy postmenopausal women, hormone therapy appears to have a beneficial effect on fasting glucose levels in women with elevated fasting insulin concentrations.[48] Also, in women with coronary artery disease, hormone therapy reduces the incidence of diabetes by 35%.[49] These findings provide important insights into the metabolic effects of hormone therapy but are insufficient to recommend the long-term use of hormone therapy in women with diabetes.

Body Weight A meta-analysis of randomized controlled trials showed that unopposed estrogen or estrogen combined with a progestogen has no effect on body weight, suggesting that hormone therapy does not cause weight gain in excess of that normally observed at the time of menopause.[50]

RISKS OF HORMONE THERAPY

The risks of hormone therapy include ovarian cancer, endometrial cancer, breast cancer, venous thromboembolism, gallbladder disease, and possibly cardiovascular disease in older women. The risks depend on the hormonal regimen used (estrogen only versus estrogen plus progestogen), the route of administration, dose, duration of therapy, age at treatment initiation, and the patient's other risk factors.

Cardiovascular Disease

6 Cardiovascular disease, including coronary artery disease, stroke, and peripheral vascular disease, is the leading cause of death among women. The American Heart Association recommends that post-menopausal hormone therapy should not be used for reducing the risk of coronary heart disease.[51]

In the previous decade, an expectation of coronary benefit had been a major reason for use of postmenopausal hormones because observational studies indicated that women who use hormone therapy have a 35% to 50% lower risk of coronary heart disease than nonusers.[52] In addition, previous studies have shown that estrogen exerts protective effects on the cardiovascular system, including lipid-lowering,[53] antioxidant,[54] and vasodilating effects.[54] Nevertheless, recent randomized clinical trials have provided no evidence of cardiovascular disease protection and even some evidence of harm with hormone therapy.[17,55–58]

The primary findings of the estrogen plus progestogen arm of the WHI trial showed an overall increase in the risk of CHD (HR 1.29, 95% CI 1.02–1.63) among healthy postmenopausal women 50 to 79 years old receiving combined estrogen–progestogen hormone therapy compared with those receiving placebo.[17] The primary findings of the estrogen-only arm of the WHI trial show no effect (either increase or decrease) on the risk of coronary heart disease in women taking estrogen alone.[18] Subgroup analyses performed in the years after the WHI was first published in 2002 and revealed that women who initiated hormone therapy 10 or more years after the time of menopause tended to have increased CHD risk compared with women who initiated therapy within 10 years of menopause.[59,60] Neither estrogen alone or estrogen plus progestogen were associated with a statistically significant effect on CHD in women aged 50–59 years, and hormone therapy was associated with reduced overall mortality, although this decrease was not statistically significant.[59]

More recently, new analyses from the WHI that included only adherent study participants found that the risk of CHD with estrogen plus progestogen use is increased in the first two years of treatment, even in women aged 50–59 years at study entry. However, the risk of CHD in women who initiated therapy within 10 years of menopause appears to decrease after six years of treatment.[60] It is important to remember that all of the above data from the WHI are from secondary analyses. In addition, the mean age of study participants was 63, while the average age of natural menopause is 51. Most women who commence estrogen or estrogen plus progestogen therapy do so within the first few years of becoming menopausal. It is still unclear how the cardiovascular effects of hormone therapy during perimenopause/early menopause and late menopause differ. There is a need for a long-term randomized controlled study of low-dose hormone therapy started around the time of menopause.[61] Hormone therapy should not be initiated or continued for the prevention of cardiovascular disease. Adherence to a healthful lifestyle

(cessation of smoking, regular exercise, healthy diet, and body mass index less than 25 kg/m^2) may prevent the onset of cardiovascular disease in postmenopausal women.[62,63]

In the estrogen plus progestogen arm of the WHI study, the increased risk for stroke and venous thromboembolism continued throughout the 5 years of therapy.[17] Increased risk was observed only for ischemic stroke and not for hemorrhagic stroke.[64] In the estrogen-alone arm of the study, a similar increased risk for stroke was observed.[18]

Breast Cancer

The WHI trial found that combined estrogen plus progestogen therapy has an increased risk of invasive breast cancer (HR 1.26, 95% CI 1.0–1.59) and a trend toward increasing risk with increasing duration of therapy.[17] The estrogen-only arm of the WHI trial found no increased risk for breast cancer during the 7-year follow-up period.[18] In the estrogen plus progestogen arm, the increased breast cancer risk did not appear until after 3 years of study participation.[17] The risk was seen only in women who initiated therapy within 5 years of the start of menopause but not in those who started therapy more than 5 years after menopause.[65] The breast cancers diagnosed in women in the hormone therapy group had similar histology and grade but were more likely to be in an advanced stage compared with women in the placebo group.[66] The risk of breast cancer returns to baseline rapidly after discontinuation of hormone therapy.[67] In an unselected postmenopausal population, the Million Women Study found that current use of hormone therapy increased breast cancer risk and breast cancer mortality (relative risk 1.66 and 1.22, respectively). Increased incidence was observed for estrogen-only use (relative risk 1.30), for estrogen plus progestogen (relative risk 2), and for tibolone (relative risk 1.45).[19]

For women in the United States, the lifetime risk of developing breast cancer is approximately one in eight,[68] and the greatest incidence occurs in women older than 60 years (see Chap. 136). In a collaborative re-analysis of data from 51 studies evaluating 52,705 women with breast cancer and 108,411 controls, less than 5 years of combined estrogen–progestogen therapy was associated with a 15% increase in breast cancer risk, and the risk increased with longer duration (relative risk 1.35 with 5 or more years of use).[69] However, 5 years after discontinuation of hormone therapy, the risk of breast cancer was no longer increased.[69]

Addition of progestogens to estrogen may increase breast cancer risk beyond that observed with estrogen alone.[70] The Iowa Women's Health Study showed that exposure to hormone therapy is associated with an increased risk of breast cancer that has a favorable prognosis.[71] These findings have been attributed to increased breast cancer screening in women taking hormone therapy. A study of the effects of hormone therapy in women with a family history of breast cancer found that those who were currently receiving hormone therapy had approximately the same increased relative risk as those who did not have a family history.[72] The overall mortality for women with a family history of breast cancer from all causes was reduced significantly among hormone therapy users.[72] These data suggest that hormone therapy use in women with a family history of breast cancer is not associated with a significantly increased incidence of the disease.

Sex steroid deficiency during menopause results in lipomatous involution of the breast, which is seen as decreased mammographic breast density and markedly improved radiotransparency of breast tissue. Thus, mammographic changes indicating breast cancer can be recognized more easily and earlier after the menopause. Conversely, combination hormone therapy results in increased mammographic breast density, and increased density on mammography has been associated with higher breast cancer risk.[73] Of note, increased mammographic density is not observed with estrogen-only therapy.[74]

Endometrial Cancer

The WHI trial suggests that combined hormone therapy does not increase endometrial cancer risk compared with placebo (HR 0.81, 95% CI 0.48–1.36).[75] Estrogen alone given to women with an intact uterus significantly increases uterine cancer risk.[76] The excess risk increases with dose and duration of estrogen (10 years of unopposed estrogen increases the risk 10-fold), is apparent within 2 years of the start of treatment, and persists for many years after estrogen replacement is discontinued.[76] Estrogen-induced endometrial cancer usually is of a low stage and grade at the time of diagnosis,[23] and it can be prevented almost entirely by progestogen coadministration. The sequential addition of progestogen to estrogen for at least 10 days of the treatment cycle or continuous combined estrogen–progestogen does not increase the risk of endometrial cancer.[77]

Lower doses of estrogen may be associated with a lower risk of endometrial hyperplasia.[78] Raloxifene does not result in endometrial hyperplasia, has no effect on endometrial thickness, is not associated with polyp formation, and has virtually no proliferative effect on the endometrium.[79] A 4-year trial of raloxifene in women with osteoporosis showed no increased risk of endometrial cancer.[80]

Ovarian Cancer

Lifetime risk of ovarian cancer is low (1.7%). The WHI trial suggests that combined hormone therapy may increase the risk of ovarian cancer (HR 1.58, 95% CI 0.77–3.24).[75] However, an observational study reported an increased risk of ovarian cancer in women taking postmenopausal estrogen-only therapy for more than 10 years (relative risk 1.8, 95% CI 1.1–3.0 and 3.2, 95% 1.7–5.7 for 10 to 19 years and 20 or more years, respectively) but no increased risk of ovarian cancer among women receiving combination estrogen–progestogen therapy.[81] A large prospective cohort study in Danish women found that use of hormone therapy was associated with an increased risk of ovarian cancer regardless of duration of use, formulation, dose of estrogen, progestogen type, hormone therapy regimen, and route of administration.[82]

Venous Thromboembolism

Venous thromboembolism, including thrombosis of the deep veins of the legs and embolism to the pulmonary arteries, is uncommon in the general population. The absolute risk of venous thromboembolism in nonhormone therapy users is approximately 1 in 10,000 women.[83] Women taking combined estrogen–progestogen hormone therapy have a twofold increased risk for thromboembolic events, with the highest risk occurring in the first year of use.[84] The absolute increase in risk is small, with 1.5 venous thromboembolic events per 10,000 women in 1 year.[84] Lower doses of estrogen are associated with a decreased risk for thromboembolism as compared with higher doses.[83] Oral administration of estrogen increases the risk of venous thromboembolism compared to the transdermal route.[85] Also, the norpregnane progestogens, unlike micronized progesterone and pregnane derivatives (e.g., medroxyprogesterone acetate), appear to be thrombogenic.

Currently, there is no indication for thrombophilia screening before initiating hormone therapy. However, hormone therapy should be avoided in women at high risk for thromboembolic events.

Gallbladder Disease

Gallbladder disease is a commonly cited complication of oral estrogen use. The WHI studies reported an increased risk for cholecystitis, cholelithiasis, and cholecystectomy among women taking

oral estrogen or estrogen–progestogen therapy.[86] Transdermal estrogen is an alternative to oral therapy for women at high risk for cholelithiasis.

Estrogens

Estrogens are naturally occurring hormones or synthetic steroidal or nonsteroidal compounds with estrogenic activity. The primary accepted indication for estrogen-based hormone therapy is the relief of vasomotor symptoms, and the initial dose should be the lowest effective dose for symptom control.

Adverse Effects Common adverse effects of estrogen include nausea, headache, breast tenderness, and heavy bleeding. More serious adverse effects include increased risk for CHD, stroke, venous thromboembolism, breast cancer, and gallbladder disease.

Initiating therapy with low doses of estrogen often will minimize breast tenderness, unscheduled bleeding, and potentially other adverse effects. Transdermal estradiol is less likely than oral estrogen to cause nausea and headache. Also, transdermal estradiol is associated with a lower incidence of breast tenderness and deep vein thrombosis than is oral estrogen.[23,87,88] In many cases changing from one estrogen regimen to another can alleviate certain adverse effects. Lower dose estrogen therapy is also associated with less mastalgia.

Dose and Administration Various systemically administered estrogens (typically oral and transdermal) are suitable for replacement therapy (Tables 91–1 and 91–2). Estrogens can be administered orally, percutaneously (transdermal patches and topical products), intravaginally (creams, tablets, or rings), intramuscularly, and even subcutaneously in the form of implanted pellets. The choice of estrogen delivery (product, route, and method) should be determined in consultation with the patient to ensure acceptability and enhance adherence. In general, the oral and transdermal routes are used most frequently, with oral conjugated equine estrogens (CEEs) particularly popular in the United States. No evidence indicates that one estrogen compound is more effective than another in relieving menopausal symptoms or preventing osteoporosis.

Oral Estrogen Oral CEE has been available for more than 50 years. CEE is prepared from the urine of pregnant mares and is composed of estrone sulfate (50% to 60%) and multiple other equine estrogens such as equilin and 17α-dihydroequilin.[89]

Estradiol is the predominant and most active form of endogenous estrogens. A micronized form of estradiol (produced by a technique that yields extremely small particles of the pure hormone) is readily absorbed from the small intestines.[89] When given orally, estradiol is metabolized by the intestinal mucosa and the liver during the first hepatic passage, and only 10% reaches circulation as free estradiol. Metabolism of estrogen is partly mediated by the cytochrome P450 3A4 isoenzyme. Gut and liver metabolism converts a large proportion of estradiol to the less potent estrone. Thus, measurement of serum estradiol is not useful for monitoring oral estrogen replacement. The principal metabolites of micronized estradiol are estrone and estrone sulfate. Administration of estradiol via the oral route results in estrone concentrations that are three to six times those of estradiol. Ethinyl estradiol is a highly potent semisynthetic estrogen that has similar activity following administration by the oral or parenteral route.

Orally administered estrogens stimulate the synthesis of hepatic proteins and increase the circulating concentrations of sex hormone–binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens.

Other Routes Non-oral forms of estrogens (including transdermal, topical, and intravaginal) bypass the gastrointestinal tract and thereby avoid first-pass liver metabolism. These routes of estradiol delivery result in a more physiologic estradiol-to-estrone ratio (estradiol concentrations greater than estrone concentrations), as seen in the normal premenopausal state. Transdermal estrogen therapy also is less likely to affect sex hormone–binding globulin

TABLE 91-1 Systemic and Topical Estrogen Products[a,b,c]

Estrogen	Dosage Strength	Comments
Oral estrogens		
Conjugated equine estrogens (Premarin)	0.3, 0.45, 0.625, 0.9, 1.25 mg	Orally administered estrogens stimulate synthesis of hepatic proteins and increase circulating concentrations of sex hormone-binding globulin, which, in turn, may compromise the bioavailability of androgens and estrogens
Synthetic conjugated estrogens (Cenestin, Enjuvia)	0.3, 0.45, 0.625, 0.9, 1.25 mg	
Esterified estrogens (Menest)	0.3, 0.625, 1.25, 2.5 mg	
Estropipate (piperazine estrone sulfate) (Ogen, Ortho-Est, generics)	0.625, 1.25, 2.5, 5[d] mg	
Micronized 17β-estradiol (Estrace, generics)	0.5, 1,1.5[d], 2 mg	
Estradiol acetate (Femtrace)	0.45, 0.9, 1.8 mg	
Transdermal estrogens[e]		
17β-estradiol transdermal patch (Alora, Climara, Esclim, Menostar, Vivelle, Vivelle Dot, generics)	14, 25, 37.5, 50, 60, 75,100 mcg per 24 h	Administered once or twice weekly depending on product
Topical estrogens[e]		
17β-estradiol topical emulsion (Estrasorb)	4.35 mg of estradiol hemihydrate per foil-laminated pouch	Single approved dose is 8.7 mg of estradiol hemihydrate per day (two pouches), which delivers 0.05 mg of estradiol per day. Apply to legs.
17β-estradiol topical gel (EsroGel, Elestrin, Divigel)	0.25 to 1 mg of estradiol per dose	Apply to either arm or thigh (depending on product) once daily
17β-estradiol transdermal spray (Evamist)	1.53 mg of estradiol per spray	1–3 sprays on inner surface of forearm once daily
Vaginal estrogens[e]		
Conjugated equine estrogens vaginal cream (Premarin)	0.625 mg conjugated equine estrogens per g	0.5–2 g per day
17β-estradiol vaginal cream (Estrace)	0.1 mg of estradiol per g	Maintenance dose is 1 g per day
17β-estradiol vaginal ring (Estring)	0.0075 mg per 24 h	Replaced every 90 days
Estradiol acetate vaginal ring (Femring)	0.05, 0.1 mg per 24 h	Replaced every 90 days
Estradiol hemihydrate vaginal tablet (Vagifem)	0.01, 0.025 mcg estradiol per tablet	Maintenance dose is 1 tablet twice weekly

[a]Systemic oral and transdermal estrogen and progestogen combination products are available in the United States.
[b]Systemic oral estrogen and androgen combination products are available in the United States.
[c]U.S. brand names.
[d]Not available in the United States.
[e]Women with elevated triglyceride concentrations or significant liver function abnormalities are candidates for non-oral estrogen therapy.

TABLE 91-2 Systemic Estrogen Products for Treatment of Menopausal Symptoms

Regimen	Standard Dose	Low Dose	Route	Frequency
Conjugated equine estrogens	0.625 mg	0.3 or 0.45 mg	Oral	Once daily
Synthetic conjugated estrogens	0.625 mg	0.3 mg	Oral	Once daily
Esterified estrogens	0.625 mg	0.3 mg	Oral	Once daily
Estropipate (piperazine estrone sulfate)	1.25 mg	0.625 mg	Oral	Once daily
Estradiol acetate	0.9 mg	0.45 mg	Oral	Once daily
Micronized 17β-estradiol	1–2 mg	0.25–0.5 mg	Oral	Once daily
Transdermal 17β-estradiol patch	50 mcg	25 mcg	Transdermal	Once or twice weekly
Implanted 17β-estradiol[a]	50–100 mg pellets	25 mg pellets	Pellets implanted subcutaneously	Every 6 months
17β-estradiol topical emulsion	2 pouches	–	Topical	Once daily
17β-estradiol topical gel	0.5–0.75 mg (depends on product)	Depends on product	Topical	Once daily
17β-estradiol transdermal spray	2–3 sprays	1 spray	Topical	Once daily
Estradiol acetate vaginal ring	12.4 mg ring (delivers 0.05 mg per day)	–	Intravaginally	Every 3 months

[a]Not available in the United States.

compared with oral therapy. These regimens produce little or no change in circulating lipids, coagulation parameters, or C-reactive protein levels.[90]

Transdermal estrogens share the advantages of other non-oral estrogen routes and have the added advantage of delivering estradiol to the general venous circulation at a continuous rate. Reactions at the application site occur in approximately 10% of women who use reservoir (alcohol-based) patches. The newer matrix systems (estrogen in adhesive) generally are better tolerated, and fewer than 5% of women experience skin reactions.[91] The incidence of skin irritation diminishes when the application site is rotated. Topical antiinflammatory products (e.g., hydrocortisone cream) can be applied for managing the rashes, and switching to another transdermal patch is often a viable option.

Topical preparations (gels, sprays, and emulsions) are convenient, but variability in drug absorption is common. This form of estrogen is also used for systemic therapy.

Estradiol pellets (implants) containing pure crystalline 17β-estradiol have been available for more than 50 years. They are inserted subcutaneously into the anterior abdominal wall or buttock. Pellets are difficult to remove and may continue to release estradiol for a long time after insertion. Implantation should not be repeated until serum estradiol concentrations have fallen to values similar to those at the midfollicular phase of the menstrual cycle. Estradiol pellets are not available in the United States.

Intravaginal creams, tablets, and rings are used for treatment of urogenital (vulval and vaginal) atrophy. However, this route of administration can have more than just a local effect. Systemic estrogen absorption is lower with vaginal tablets and rings (specifically Estring) compared with vaginal creams. Nonetheless, local application of the cream at low doses can reverse atrophic vaginal changes and avoid significant systemic exposure. Nonestrogen vaginal moisturizers and lubricants also may provide local symptom relief. These products can be used alone or in combination with locally-acting intravaginal estrogens. Intravaginal rings are a sustained-release delivery system composed of a biologically inert liquid polymer matrix with pure crystalline estradiol that can maintain adequate estradiol concentrations. One such intravaginal ring product (Femring) is designed to achieve systemic concentrations of estrogen and is indicated for treatment of moderate to severe vasomotor symptoms.

Progestogens

7 Because of the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (unopposed estrogen), women who have not undergone hysterectomy should be treated concurrently with a progestogen in addition to the estrogen.[92]

Progestogens reduce nuclear estradiol receptor concentrations, suppress DNA synthesis, and decrease estrogen bioavailability by increasing the activity of endometrial 17-hydroxysteroid dehydrogenase, an enzyme responsible for converting estradiol to estrone.[76]

The first generation of progestogens included the C-19 androgenic progestogens norethindrone (also known as norethisterone), norgestrel, and levonorgestrel. More recent preparations have included the C-21 progestogens dydrogesterone and medroxyprogesterone acetate, which are less androgenic. Drospirenone, a synthetic progestogen analog of the potassium-sparing diuretic spironolactone, has both antiandrogenic and antialdosterone properties. Micronized progesterone also has become available for use in postmenopausal women. The most commonly used oral progestogens are medroxyprogesterone acetate, micronized progesterone, and norethindrone acetate. The latter now can be administered transdermally in the form of a combined estrogen–progestogen patch.

Adverse Effects Common adverse effects of progestogens include irritability, depression, and headache. Changing from a cyclic to a continuous-combined regimen or changing from one progestogen to another may decrease the incidence or severity of untoward effects. Adverse effects of progestogens are difficult to evaluate and can vary with the agent administered. Some women experience "premenstrual-like" symptoms, such as mood swings, bloating, fluid retention, and sleep disturbance. New methods and routes of progestogen delivery (e.g., by an intranasal spray or locally by an intrauterine device that releases levonorgestrel or a progesterone-containing bioadhesive vaginal gel) may be associated with fewer adverse effects. Women who are unable to tolerate a progestogen may be given unopposed estrogen if they are informed of the significant increased risk for endometrial cancer and have endometrial biopsy annually or whenever breakthrough vaginal bleeding occurs.

Dose and Administration Several progestogen regimens designed to prevent endometrial hyperplasia are available (Table 91–3). Progestogens must be taken for a sufficient period of time during each cycle. A minimum of 12 to 14 days of progestogen therapy each month is required for complete protection against estrogen-induced endometrial hyperplasia.[93] Of note, use of even low-dose estrogen, including some intravaginal preparations, requires progestogen coadministration for endometrial protection in women with an intact uterus.[94] However, rarely is progestogen administration needed in women who have undergone hysterectomy.

Methods of Combined Estrogen and Progestogen Administration

Four combination estrogen and progestogen regimens currently in use are continuous cyclic (sequential), continuous combined,

TABLE 91-3 Progestogen Doses for Endometrial Protection (Oral Cyclic Administration)

Progestogen	Dose
Dydrogesterone[a]	10–20 mg for 12–14 days per calendar month
Medroxyprogesterone acetate	5–10 mg for 12–14 days per calendar month
Micronized progesterone	200 mg for 12–14 days per calendar month
Norethindrone (norethisterone)[b]	0.7–1 mg for 12–14 days per calendar month
Norethindrone acetate	5 mg for 12–14 days per calendar month
Norgestrel[c]	0.15 mg for 12–14 days per calendar month
Levonorgestrel[d]	150 mcg for 12–14 days per calendar month

[a]Not available in the United States.
[b]In the United States, available in a progestogen-only oral dosage form as 0.35 mg tablets approved for prevention of pregnancy.
[c]Not available in a progestogen-only oral dosage form in the United States.
[d]In the United States, available in a progestogen-only oral dosage form as 75 mcg tablets approved for emergency contraception.

continuous long-cycle (or cyclic withdrawal), and intermittent combined (or continuous-pulsed) hormone therapy.[95] The latter two were introduced during the past decade. Sequential hormone therapy results in scheduled vaginal withdrawal bleeding but often is scant or completely absent in older women. For many women, scheduled withdrawal bleeding is one of the main reasons for avoiding or discontinuing hormone therapy. Because there is no physiologic need for bleeding, new hormone therapy regimens that reduce monthly bleeding (e.g., continuous long-cycle regimens) or prevent monthly bleeding (e.g., continuous combined and intermittent combined regimens) have been developed. Various hormone therapy regimens that combine an estrogen and a progestogen are available (Table 91–4).

Continuous Cyclic Estrogen–Progestogen (Sequential) Treatment Estrogen typically is administered continuously (daily). A progestogen is coadministered with the estrogen for at least 12 to 14 days of a 28-day cycle.[93] The progestogen causes scheduled withdrawal bleeding in approximately 90% of women. With this regimen, bleeding usually begins 1 to 2 days after the last progestogen dose. Occasionally, bleeding begins during the latter phase of progestogen administration.

Continuous Combined Estrogen–Progestogen Treatment Continuous combined estrogen–progestogen administration results in endometrial atrophy and the absence of vaginal bleeding. However, initially it causes unpredictable spotting or bleeding, which usually resolves within 6 to 12 months. Decreasing the estrogen dose or increasing the progestogen dose usually decreases or stops the spotting. Occasionally, a drug-free period of 1 or 2 weeks is useful to stop the bleeding.

Women who recently have undergone menopause have a higher risk for excessive, unpredictable bleeding while receiving continuous therapy; thus, this regimen is best reserved for women who are at least 2 years postmenopause. Continuous combined hormone therapy is more acceptable than traditional cyclic therapy.

Continuous Long-Cycle Estrogen–Progestogen Treatment In order to decrease the incidence of uterine bleeding, a modified sequential regimen has been developed.[95] In the continuous long-cycle (or cyclic withdrawal) estrogen–progestogen regimen, estrogen is given daily, and progestogen is given six times per year, every other month for 12 to 14 days, resulting in six periods per year. Bleeding episodes may be heavier and last for more days than withdrawal bleeding with continuous cyclic regimens. The effect of continuous long-cycle estrogen–progestogen treatment on endometrial protection is unclear.

Intermittent Combined Estrogen–Progestogen Treatment The intermittent combined estrogen–progestogen regimen, also called *continuous-pulsed estrogen–progestogen* or *pulsed-progestogen*, consists of 3 days of estrogen therapy alone, followed by 3 days of combined estrogen and progestogen, which is then repeated without interruption.[95] This regimen is designed to lower the incidence of uterine bleeding. It is based on the assumption that pulsed-progestogen administration will prevent down-regulation of progesterone receptors that can be produced by continuous combined regimens. The lower progestogen dose induces fewer side effects and can be better tolerated. The long-term effect of intermittent combined regimens in endometrial protection is undetermined.

TABLE 91-4 Common Combination Postmenopausal Hormone Therapy Regimens

Regimen	Doses
Oral continuous-cyclic regimens	
CEE + MPA[a]	0.625 mg + 5 mg; 0.625 mg + 10 mg
Oral continuous-combined regimens	
CEE + MPA	0.625 mg + 2.5 mg; 0.625 mg + 5 mg; 0.45 mg + 2.5 mg; 0.3 mg + 1.5 mg/day
17β-Estradiol + NETA	1 mg + 0.1 mg;1 mg + 0.25 mg; 1 mg + 0.5 mg/day
Ethinyl estradiol + NETA	1 mcg + 0.2 mg; 2.5 mcg + 0.5 mg; 5 mcg + 1 mg; 10 mcg + 1 mg/day
Transdermal continuous-cyclic regimens	
17β-Estradiol + NETA[a]	50 mcg + 0.14 mg; 50 mcg + 0.25 mg
Transdermal continuous-combined regimens	
17β-Estradiol + NETA	50 mcg + 0.14 mg; 50 mcg + 0.25 mg; 25 mcg + 0.125 mg

CEE, conjugated equine estrogens; MPA, medroxyprogesterone acetate; NETA, norethindrone acetate.
Other oral (drospirenone and norgestimate) and transdermal (levonorgestrel) progestogens also are available in combination with an estrogen.
[a]Estrogen alone for days 1–14, followed by estrogen–progestogen on days 15–28.

Low-Dose Hormone Therapy

8 Increasingly, it has become recognized that use of hormone therapy at doses lower than those prescribed historically is effective in the management of menopausal symptoms (see Table 91–2). The standard dose of estrogen previously believed to be effective in alleviating vasomotor symptoms is equivalent to 0.625 mg CEE,[36] but new evidence indicates that lower doses of estrogen also are effective in controlling postmenopausal symptoms and reducing bone loss.[96–99] The Women's Health, Osteoporosis, Progestin, Estrogen (HOPE) trial demonstrated equivalent symptom relief and bone density preservation without an increase in endometrial hyperplasia using lower doses of hormone therapy (CEE 0.45 mg/day and medroxyprogesterone acetate 1.5 mg/day).[97–99] Even ultralow doses of 17β-estradiol delivered by a vaginal ring (Estring) improved serum lipid profiles and prevented bone loss in elderly women.[100] Whether lower doses of estrogen will be safer (lower incidence of venous thromboembolism and breast cancer) remains to be proven. Nonetheless, evidence of harm associated with a standard dose of hormone therapy[17,18] has prompted many patients to either discontinue such therapy or taper to lower doses. In general, if adverse effects such as breast tenderness occur with initial doses, lowering the dose may resolve the problem and improve patient adherence. Alternatively, if vasomotor symptoms are not controlled adequately with a lower-dose regimen, increasing the estrogen dose may be a reasonable option.

CLINICAL CONTROVERSY

Although some clinicians believe that estrogen can be used safely at lower doses to treat postmenopausal women with severe and protracted vasomotor symptoms, others caution that such long-term therapy, even with lower doses of estrogen, may be associated with unacceptable risks.

Bioidentical Hormones Bioidentical hormone therapy has received much attention by patients, health care professionals, and the media since the initial publication of the WHI results. Bioidentical hormone therapy refers to the practice of using natural (e.g., estrone, estradiol, estriol progesterone, and testosterone), rather than synthetic, formulations of sex hormones. Often, these hormones are compounded to make a variety of topical formulations, in theory to individualize hormone therapy based on each patient's specific physiologic hormone levels as measured via salivary concentrations. This strategy is thought to reduce the risk of adverse effects. However, there is a paucity of evidence regarding both their efficacy and safety.[101] Biodentical hormones appear to carry the same risks as traditional hormone therapy. Several major medical organizations, along with the FDA, have released statements that dissuade against the use of this treatment strategy.[102,103]

ALTERNATIVE DRUG TREATMENTS

In women who have contraindications to estrogen and progestogen use, prefer not to take estrogen and/or progestogen, or cannot tolerate estrogen and/or progestogen administration, a number of other medications may be considered, depending on the goals of therapy. These include the prescription medications testosterone, raloxifene, and tibolone (not currently available in the United States) as well as nonhormonal prescription medications (e.g., selective serotonin reuptake inhibitors). Some women prefer to use herbals and other natural therapies but the efficacy and safety of these methods have not been definitively established.

Alternatives to estrogen for treatment of hot flushes include tibolone, selective serotonin reuptake inhibitors (e.g., paroxetine, fluoxetine), dual serotonin and noradrenaline reuptake inhibitors (e.g., venlafaxine), medroxyprogesterone acetate, megestrol acetate, clonidine, and gabapentin (Table 91–5).[104] Progestogens alone may be an option for some women (e.g., those with a history of breast cancer or venous thrombosis), but weight gain, vaginal bleeding, and other adverse effects often limit their use. Tibolone and progestogens cannot be considered nonhormonal agents for treatment of hot flushes in women for whom hormone therapy is contraindicated. For this group of patients, selective serotonin reuptake inhibitors and venlafaxine are considered by some to be a first-line therapy.[104,105] However, the efficacy of venlafaxine for treatment of hot flushes has not been shown to extend beyond 12 weeks.[106] Furthermore, in breast cancer patients, evidence suggests that selective serotonin reuptake inhibitors could interfere with metabolism of endocrine therapies, such as tamoxifen via cytochrome P450 2D6 inhibition.[107] Clonidine is often effective for symptom control, but its side effects (e.g. sedation, dry mouth, hypotension) are not always well tolerated by women.

Androgens

Pathophysiologic states affecting ovarian and adrenal function, along with aging, have been associated with androgen deficiency in women.[108] The therapeutic use of testosterone in women, although controversial, is becoming more widespread despite the lack of accurate clinical or biochemical findings of androgen deficiency.[108] Androgens have important biologic effects in women, acting both directly via androgen receptors in tissues, such as bone, skin fibroblasts, hair follicles, and sebaceous glands, and indirectly via the aromatization of testosterone to estrogen in the ovaries, bone, brain, adipose tissue, and other tissues.

Efficacy A cluster of symptoms that characterizes androgen insufficiency in women, manifested as diminished sense of well-being, persistent or unexplained fatigue, and sexual function changes such as decreased libido, decreased sexual receptivity, and decreased pleasure, has been reported.[108] However, studies designed to evaluate this have shown no relationships between serum total and free testosterone levels and either sexual function[109] or well-being[110] in women. Thus, as data supporting an androgen deficiency syndrome are lacking, in 2006 the American Endocrine Society recommended against making a diagnosis of androgen deficiency in women at the present time.[109] Several large randomized placebo-controlled clinical trials involving naturally[111,112] and surgically[113] postmenopausal women presenting with low libido demonstrate that testosterone therapy, with and without concurrent estrogen therapy, improves the quality of the sexual experience, with preliminary data that this may also apply to premenopausal women.[114]

Adverse Effects Absolute contraindications to androgen therapy include pregnancy or lactation and known or suspected androgen-dependent neoplasia. Relative contraindications include concurrent use of CEEs (for parenteral testosterone therapy), low sex hormone–binding globulin level (below the normal range for women) moderate to severe acne, clinical hirsutism, and androgenic alopecia.

Adverse effects from excessive dosage include virilization, fluid retention, and potentially adverse lipoprotein lipid effects, which are more likely with oral administration. There is no evidence that systemic transdermal testosterone is associated with increased

TABLE 91-5 Alternatives to Estrogen for Treatment of Hot Flushes

Drug	Dose (Oral)	Interval	Comments
Tibolone[a]	2.5–5 mg	Once daily	Tibolone is not recommended during the perimenopause because it may cause irregular bleeding
Venlafaxine	37.5–150 mg	Once daily	Side effects include dry mouth, decreased appetite, nausea, and constipation
Paroxetine	12.5–25 mg	Once daily	12.5 mg is an adequate, well-tolerated starting dose for most women; adverse effects include headache, nausea, and insomnia
Fluoxetine	20 mg	Once daily	Modest improvement seen in hot flushes
Megestrol acetate	20–40 mg	Once daily	Progesterone may be linked to breast cancer etiology; also, there is concern regarding the safety of progestational agents in women with preexisting breast cancer
Clonidine	0.1 mg	Once daily	Can be administered orally or transdermally; drowsiness and dry mouth can occur, especially with higher doses
Gabapentin	900 mg	Divided in 3 daily doses	Adverse effects include somnolence and dizziness; these symptoms often can be obviated with a gradual increase in dosing

[a]Not available in the United States.

TABLE 91-6 Androgen Regimens Used for Women

Regimen	Dose	Frequency	Route
Methyltestosterone in combination with esterified estrogen	1.25–2.5 mg	Daily	Oral
Mixed testosterone esters	50–100 mg	Every 4–6 weeks	Intramuscular
Testosterone pellets	50 mg	Every 6 months	Subcutaneous (implanted)
Transdermal testosterone system[a]	150–300 mcg/day	Every 3–4 days	Transdermal patch
Nandrolone decanoate	50 mg	Every 8–12 weeks	Intramuscular

[a]Undergoing clinical trials in the United States.

cardiovascular morbidity or mortality[115] or of a significant change in the risk of invasive breast cancer.[116,117] However, further studies are required to determine the long term safety of testosterone in women.

Dose and Administration Testosterone is available as oral methyltestosterone in the United States and as testosterone implants in the United Kingdom. Of the available oral preparations, methyltestosterone in combination with esterified estrogen (either 0.625 mg esterified estrogen plus 1.25 mg methyltestosterone or 1.25 mg esterified estrogen plus 2.5 mg methyltestosterone) is the most widely studied.

Testosterone replacement for women is available in a variety of formulations (Table 91–6). Most of the earlier studies showing clinical improvement with testosterone therapy reported supraphysiologic levels. More recent studies using transdermal patch therapy have shown efficacy with free testosterone levels in the upper normal range for young women. The availability of testosterone regimens specifically designed for women has the potential to maintain testosterone levels within the normal range and help to clarify whether the apparent beneficial effects of testosterone therapy are physiologic or pharmacologic.[113,118] In general, testosterone treatment can be administered to postmenopausal women with and without concurrent estrogen therapy. At present, generalized use of testosterone is not recommended because the indications are inadequate, and evidence from long-term studies evaluating safety is lacking.[119]

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators (SERMs) are a group of nonsteroidal compounds that are chemically distinct from estradiol. They act as estrogen agonists in some tissues, such as bone, and as estrogen antagonists in other tissues, such as breast, through specific, high-affinity binding to the estrogen receptor.

Efficacy The ideal SERM would protect against osteoporosis and decrease the incidence of breast, endometrial, and colorectal cancer and coronary heart disease without exacerbating menopausal symptoms or increasing the risk of venous thromboembolism or gallbladder disease. To date, no SERM meets these ideals. Tamoxifen, the first-generation SERM (a nonsteroidal triphenylethylene derivative), has estrogen antagonist activity on the breast and estrogen-like agonist activity on bone and endometrium. The second generation of SERMs, most notably raloxifene (a nonsteroidal benzothiophene derivative), has become available for prevention of osteoporosis. Raloxifene does not alleviate, and may even exacerbate, vasomotor symptoms.

The Multiple Outcomes of Raloxifene Evaluation (MORE), a multicenter randomized, blinded, placebo-controlled trial, showed that raloxifene increases BMD in the spine and femoral neck and reduces the risk of vertebral fractures.[120] It has not been shown to decrease the risk of hip fractures. Raloxifene decreases bone loss in recently menopausal women without affecting the endometrium and has estrogen-like actions on lipid metabolism.[120] More importantly, the same study[121] and the Continuing Outcomes Relevant to Evista (CORE) trial[122] suggest that raloxifene use is associated with a significantly lower incidence of breast cancer compared with placebo. This benefit is primarily due to a reduced risk of estrogen receptor–positive invasive breast cancers.[80,122] A prospective randomized double-blinded trial of 19,747 women at high risk for breast cancer (Study of Tamoxifen and Raloxifene [STAR]) showed that raloxifene is as effective as tamoxifen in reducing the risk of invasive breast cancer and has a lower risk of thromboembolic events.[123] A prospective randomized study (Raloxifene Use for the Heart [RUTH]) of 10,101 postmenopausal women (mean age 67.5 years) with coronary heart disease or multiple risk factors for coronary heart disease showed that raloxifene did not significantly affect the risk of coronary heart disease.[80] Raloxifene does not have a significant effect on cognitive function; however, there is a trend toward a smaller decline in verbal memory and attention scores among women receiving raloxifene.[124]

Adverse Effects Raloxifene is commonly associated with hot flushes and less often with leg cramps. Raloxifene use increases the risk of venous thromboembolism[80,120–122] and fatal stroke[80] to a degree similar to that of oral estrogen.

Dose and Administration Raloxifene is FDA-approved for the treatment and prevention of osteoporosis and for the reduction of the risk of invasive breast cancer in postmenopausal women with osteoporosis as well as postmenopausal women at high risk for invasive breast cancer. The dose is 60 mg orally once daily.

Tibolone

Tibolone is a gonadomimetic synthetic steroid in the norpregnane family with combined estrogenic, progestogenic, and androgenic activity.[125] Tibolone has been used for 2 decades in Europe for treatment of menopausal symptoms and prevention of osteoporosis but is currently not available in the United States. The hormonal effects of this synthetic steroid depend on its metabolism and activation in peripheral tissues. The parent compound has been described as a prodrug that is metabolized quickly in the gastrointestinal tract. It has several active metabolites, including a Δ4-isomer and 3α-OH and 3β-OH compounds.[125] The Δ4-isomer metabolite confers significant progestogenic and androgenic properties.

Efficacy Tibolone has beneficial effects on mood and libido and improves menopausal symptoms and vaginal atrophy. Tibolone protects against bone loss and significantly reduces the risk of vertebral fractures in postmenopausal women with osteoporosis.[126] It has also been shown to decrease the risk of breast cancer and colon cancer in older women (aged 60–85 years) in one randomized study.[127] It is also more effective than conventional hormone therapy for management of sexual dysfunction.[128]

Adverse Effects Tibolone use in elderly women has been reported to be associated with an increased risk of stroke.[126,127] Tibolone lowers concentrations of total cholesterol, triglycerides, and lipoprotein (a) but may decrease high-density lipoprotein (HDL) cholesterol.[89] The Million Women Study, an observational cohort study, found a greater risk of endometrial cancer (adjusted relative risk 1.79, 95% CI 1.43–2.25).[129] However, other randomized placebo-controlled studies

have not shown an increased risk of endometrial cancer with tibolone and suggest that tibolone has an endometrial safety profile similar to continuous combined CEE and medroxyprogesterone acetate.[130]

The most commonly reported adverse effects of tibolone include weight gain and bloating.

Complementary and Alternative Medicine

Some women prefer to use natural remedies due to a belief that they are safer. Randomized, placebo-controlled trials of complementary and alternative therapies have been equivocal and have not established the safety and efficacy of herbal remedies, homeopathic treatments, or acupuncture for the prevention or treatment of hot flushes.

Phytoestrogens Phytoestrogens have physiologic effects in humans.[131] They are plant compounds with estrogen-like biologic activity and relatively weak estrogen receptor–binding properties. Epidemiologic studies suggest that consumption of a phytoestrogen-rich diet, which is common in traditional Asian societies, is associated with a lower risk of breast cancer.[131]

The biologic potencies of phytoestrogens vary. Most of these compounds are nonsteroidal and are less potent than synthetic estrogens. The three main classes of phytoestrogens are isoflavones, lignans, and coumestans, all of which are found in plants or their seeds.[131] The most commonly studied phytoestrogen is the isoflavone class. Genistein and daidzein are the most abundant active components of isoflavones. The concentration of isoflavones per gram of soy protein varies considerably among preparations. Also, a single plant often contains more than one class of phytoestrogen. Common food sources of phytoestrogens include soybeans (isoflavones), cereals, oilseeds such as flaxseed (lignans), and alfalfa sprouts (coumestans).

Mild estrogenic effects have been seen in postmenopausal women,[131] but current data suggest that phytoestrogen supplementation is no more effective than placebo in relieving hot flushes or other symptoms of menopause in postmenopausal women.[132]

Phytoestrogens decrease low-density lipoprotein (LDL) cholesterol and triglyceride concentrations with no significant change in HDL cholesterol concentrations.[133] Furthermore, phytoestrogens have the ability to inhibit LDL oxidation and normalize vascular reactivity in estrogen-deprived primates.[133] In addition, BMD may be improved by phytoestrogens.[131] Common adverse effects include constipation, bloating, and nausea.[134]

A recent meta-analysis reported that phytoestrogen use is not associated with increased rates of endometrial cancer, vaginal bleeding, and breast cancer.[134] Large, long-term studies are needed to further document the effects of phytoestrogens on the breast, bone, and endometrium. Furthermore, differences among classes of phytoestrogens must be identified clearly, including dosing and biologic activity, before phytoestrogens can be considered an alternative to conventional hormone therapy in postmenopausal women.

Other Herbal Products Black cohosh (*Cimicifuga racemosa* or *Acetaea racemosa*), a widely used herbal supplement, may not offer substantial benefits for relief of vasomotor symptoms as suggested by earlier trials.[135] This substance does not appear to have strong intrinsic estrogenic properties but may act through the serotonergic system. Black cohosh appears to be generally well tolerated, although hepatotoxicity has been reported. It is unclear if this is due to the herb itself or adulterations of commercially available products.[136] The long-term effects of black cohosh are unknown. Other herbals and alternative treatments that may be used by women include dong quai, red clover leaf (contains phytoestrogens), kava, and dehydroepiandrosterone. These have not been shown to be effective in the treatment of menopausal symptoms and may carry the risk of adverse events.[137] Complementary and alternative therapies should not be recommended to treat menopausal symptoms.

Pharmacoeconomic Considerations

Estrogens and progestogens used for postmenopausal hormone therapy are prescribed commonly in the United States, especially for the management of menopausal vasomotor symptoms. Even before publication of the WHI trial findings, only a fraction of women filled their hormone therapy prescriptions, and only 25% to 40% continued to take postmenopausal hormone therapy for more than 1 year.[138] This may be due to women's attitudes toward hormone therapy or a result of fear about adverse effects and associated risks. Hormone therapy use in the United States declined substantially after dissemination of the WHI trial results.[139]

Use of hormone therapy for the management of vasomotor symptoms is cost effective, and data supporting the use of nonhormonal alternatives are limited. The cost of hormone therapy varies depending on the route and method of delivery. Transdermal preparations are about twice as expensive as their equivalent oral preparations.[140] Women who have undergone hysterectomy use hormone therapy more frequently than do women with an intact uterus (58.7% vs 19.6%).[16]

EVALUATION OF THERAPEUTIC OUTCOMES

After the menopausal woman begins hormone therapy, a brief follow-up visit 6 weeks later may be useful to discuss patient concerns about hormone therapy and to evaluate the patient for symptom relief, adverse effects, and patterns of withdrawal bleeding. The FDA recommends that women who choose estrogen-based therapy should have yearly breast examinations, perform monthly breast self-examinations, and receive periodic mammograms (scheduled based on their age and risk factors). Also, women receiving hormone therapy should undergo annual monitoring, including a medical history, physical examination, pelvic examination, blood pressure measurement, and routine endometrial cancer surveillance, as indicated. Additional follow-up is determined based on the patient's initial response to therapy and the need for any modification of the regimen. An ultrasound, ideally transvaginal, and where indicated an endometrial biopsy should be performed in women taking cyclic hormone therapy if vaginal bleeding occurs at any time other than the expected time of withdrawal bleeding or when heavier or more prolonged withdrawal bleeding occurs. In women taking continuous combined hormone therapy, endometrial evaluation should be considered when irregular bleeding persists for more than 6 months after initiating therapy. However, there is no universal agreement that endovaginal ultrasonography is adequate for excluding endometrial pathology.

The main indication for hormone therapy is relief of menopausal symptoms, and hormone therapy should be used only as long as symptom control is necessary (typically 2–3 years). When hormone therapy is used under such conditions, the absolute risk of harm to an individual woman is very small.[17]

Many women have no difficulty abruptly stopping hormone therapy; others develop vasomotor symptoms after discontinuation. Although these symptoms usually are mild and resolve over a few months, in some women the symptoms are severe and intolerable. Few studies have addressed the appropriate method for discontinuing hormone therapy. There is no evidence that gradual discontinuation of hormone therapy reduces the recurrence of hot flushes compared with sudden discontinuation. Studies determining effective ways to reduce symptoms of estrogen withdrawal are needed.

BMD should be measured in women older than 65 years and in women younger than 65 years with risk factors for osteoporosis. Although bone densitometry has been shown to predict fractures, at present there are no guidelines for follow-up BMD testing. However, in women with significant bone loss, repeat testing should be performed as clinically indicated.

CONCLUSIONS

During the past decade, postmenopausal hormone therapy became one of the most frequently prescribed therapies in the United States. Menopause is a natural life event, not a disease. Therefore, the decision to use hormone therapy must be individualized based on the severity of menopausal symptoms, risk of osteoporosis, and consideration of factors such as cardiovascular disease, breast cancer, and thromboembolism (Table 91–7).

TABLE 91-7 Evidence-Based Hormone Therapy Guidelines for Menopausal Symptom Management

Recommendation	Recommendation Grade[a]
In the absence of contraindications, estrogen-based postmenopausal hormone therapy should be used for treatment of moderate to severe vasomotor symptoms	A1
Systemic or vaginal estrogen therapy should be used for treatment of urogenital symptoms and vaginal atrophy	A1
Hormone therapy should be prescribed at the lowest effective dose and for the shortest duration	B2
Postmenopausal women taking estrogen-based therapy should be followed-up every year, taking into account findings from new clinical trials	A1
Postmenopausal women taking estrogen-based therapy should be informed about potential risks	A1
Safety and tolerability may vary substantially with the type and regimen of hormone therapy	B2
Breast cancer risk increases after use of continuous combined hormone therapy for longer than 5 years	A1
Breast cancer risk does not increase after long-term estrogen-only therapy (6.8 years) in postmenopausal women with hysterectomy	A1
Hormone therapy should not be used for primary or secondary prevention of coronary heart disease	A1
Oral hormone therapy increases risk of venous thromboembolism	A1
Non-oral hormone therapy may be safer for postmenopausal women at risk for venous thromboembolism who choose to take hormone therapy	B2
Oral hormone therapy increases risk of ischemic stroke	A1
Although hormone therapy decreases risk of osteoporotic fractures, it cannot be recommended as a first-line therapy for the treatment of osteoporosis	A1
Potential harm (cardiovascular disease, breast cancer, and thromboembolism) from long-term hormone therapy (use greater than 5 years) outweighs potential benefits	A1
Young women with primary ovarian insufficiency have severe menopausal symptoms and increased risk for osteoporosis and cardiovascular disease. Decisions on whether and how these young women must be treated should not be based on studies of hormone therapy in women older than 50 years.	B3

Quality of evidence: 1, evidence from more than one properly randomized controlled trial; 2, evidence from more than one well-designed clinical trial with randomization from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert communities.

[a]Strength of recommendations: A, good evidence to support recommendation; B, moderate evidence to support recommendation; C, poor evidence to support recommendation.

Large prospective, randomized trials have shown that postmenopausal hormone therapy prescribed for disease prevention may cause more harm than good.[17,58] The WHI trial reported increased risk of cardiovascular disease, breast cancer, stroke, and thromboembolic disease among women using continuous combined therapy with CEE plus medroxyprogesterone acetate compared with placebo. In the estrogen-alone arm of the study, CEE had no effect on cardiovascular disease or breast cancer risk compared to placebo, but an increased risk of stroke and thromboembolic disease was noted in those who received estrogen. The WHI trial also demonstrated that quality of life and cognition were no better in the group receiving hormone therapy than in the placebo group, and that hormone therapy increases dementia risk in women 65 years or older.

Postmenopausal symptoms, such as hot flushes and vaginal dryness, remain a valid indication for hormone therapy in the absence of contraindications. For short-term use of hormone therapy for relief of menopausal symptoms, the benefits for many women outweigh the risks. For symptoms of genital atrophy alone, local estrogen and/or nonhormonal lubricants should be considered.

Long-term use of hormone therapy cannot be recommended routinely for osteoporosis prevention given the availability of alternative therapies, such as bisphosphonates and raloxifene. For long-term hormone therapy use, the potential harm (cardiovascular disease, breast cancer, and thromboembolism) outweighs the potential benefits. Hormone therapy should not be used for prevention of CHD. Women with cardiovascular risk factors (e.g., hypertension, lipid abnormalities) can benefit from reduction of these risk factors through interventions such as weight loss, lipid-lowering therapy, use of aspirin, and physical activity.

PRIMARY OVARIAN INSUFFICIENCY AND PREMENOPAUSAL HORMONE REPLACEMENT THERAPY

Primary ovarian insufficiency is a condition characterized by sex-steroid deficiency, amenorrhea, and infertility in women younger than 40 years.[141] Primary ovarian insufficiency was once considered irreversible and was described as "premature menopause" and the condition is still referred to as *premature ovarian failure*. However, primary ovarian insufficiency is not an early, natural menopause. Normal menopause results from ovarian follicle depletion, whereas primary ovarian insufficiency is characterized by intermittent ovarian function in half of affected women.[141] These women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. Pregnancies have occurred in 5% to 10% of women after the diagnosis of premature ovarian failure, even in women with no follicles observed on ovarian biopsy.

EPIDEMIOLOGY

The prevalence of primary ovarian insufficiency increases with increasing age, reaching approximately 1% of women by age 40 years.[142]

ETIOLOGY

A number of physiologic or metabolic abnormalities can lead to primary ovarian insufficiency (Table 91–8). In most cases, the etiology cannot be identified.

PATHOPHYSIOLOGY

Primary ovarian insufficiency may occur as a result of ovarian follicle dysfunction or ovarian follicle depletion and may present as either primary amenorrhea (absence of menses in a girl who

TABLE 91-8 Etiology of Primary Ovarian Insufficiency

Idiopathic: Karyotypically normal spontaneous primary ovarian insufficiency
Autoimmunity: (A) isolated autoimmune primary ovarian insufficiency or (B) as a component of an autoimmune polyglandular syndrome in association with Addison's disease, hypothyroidism, hypoparathyroidism, or mucocutaneous candidiasis
Iatrogenic: Chemotherapy, radiation, extensive ovarian surgery
X-chromosome abnormalities
Gonadotropin and gonadotropin-receptor abnormalities: Signal defects
Enzyme deficiencies: Cholesterol desmolase, 17α-hydroxylase, 17, 20-desmolase
Galactosemia
Blepharophimosis, ptosis, and epicanthus inversus syndrome type 1: Rare autosomal dominant syndrome in which primary ovarian insufficiency is the predominant syndrome
Perrault syndrome: Familial autosomal recessive primary ovarian insufficiency in association with deafness

has reached age 16 years) or secondary amenorrhea (cessation of menses in a woman previously menstruating for at least 6 months). Approximately 50% of women with primary ovarian insufficiency have documented ovarian follicle function.[141]

CLINICAL PRESENTATION

No characteristic menstrual pattern or history precedes primary ovarian insufficiency. Approximately 50% of patients with this condition have a history of oligomenorrhea or dysfunctional uterine bleeding (prodromal premature ovarian failure), and approximately 25% develop amenorrhea acutely. Some patients develop amenorrhea postpartum, whereas others experience amenorrhea after discontinuing oral contraceptives. Primary amenorrhea is not associated with symptoms of estrogen deficiency. In cases of secondary amenorrhea, symptoms may include hot flushes, night sweats, fatigue, and mood changes. Prodromal primary ovarian insufficiency may present with hot flushes even in women who menstruate regularly. Incomplete development of secondary sex characteristics may occur in women with primary amenorrhea, whereas these characteristics typically are normal in women with secondary amenorrhea. In general, women with primary ovarian insufficiency have normal fertility before the disorder develops.

Primary ovarian insufficiency is defined by the presence of at least 4 months of amenorrhea and at least two serum FSH concentrations measuring greater than 40 milliinternational units/mL (40 IU/L) (obtained at least 1 month apart) in women younger than 40 years. A complete history should be taken, considering other factors that can affect ovarian function such as prior ovarian surgery, chemotherapy, radiation, and autoimmune disorders. In patients with primary amenorrhea, particular attention should be paid to breast and pubic hair development according to Tanner stages. Short stature, stigmata of Turner syndrome, and other dysmorphic features of gonadal dysgenesis should be considered. Ideally, a pelvic examination is performed but is not always clinically appropriate. Alternatively, transabdominal ultrasonography can be performed in patients with primary amenorrhea to confirm the presence of normal anatomic structures. In the majority of cases, physical examination is completely normal. A karyotype should be performed in all patients experiencing primary ovarian insufficiency. Women with ovarian insufficiency and a karyotype containing a Y chromosome should undergo bilateral gonadectomy because of substantial risk for gonadal germ cell neoplasia.[141] Ovarian biopsy and antiovarian antibody testing are investigational procedures with no proven clinical benefit in primary ovarian insufficiency. As clinically indicated, the workup should include tests for the diagnosis of other possible associated autoimmune disorders, such as hypothyroidism, diabetes mellitus, and Addison's disease.

CLINICAL PRESENTATION OF PRIMARY OVARIAN INSUFFICIENCY

Symptoms

- Primary amenorrhea: No symptoms of estrogen deficiency
- Secondary amenorrhea: Vasomotor symptoms (hot flushes and night sweats), sleep disturbances, mood changes, sexual dysfunction, problems with concentration and memory, vaginal dryness, and dyspareunia

Signs

- Primary amenorrhea: Incomplete development of secondary sex characteristics
- Secondary amenorrhea: Normal development of secondary sex characteristics, signs of urogenital atrophy

Laboratory Tests

- FSH greater than 40 milliinternational units/mL (40 IU/L)
- Other relevant diagnostic tests (e.g., bone mineral density, ultrasound of the ovaries)
- Thyroid function tests, fasting glucose level, and adrenocorticotropic hormone stimulation test

In the majority of patients, ovarian insufficiency develops after the establishment of regular menses. Young women with primary ovarian insufficiency who develop ovarian dysfunction before they achieve peak adult bone mass sustain sex steroid deficiency for more years than do naturally menopausal women. This deficiency can result in a significantly higher risk for osteoporosis[143] and cardiovascular disease.[144,145] Importantly, a survey of more than 19,000 women between the ages of 25 and 100 years suggests that ovarian insufficiency occurring before age 40 years is associated with significantly increased mortality, with an age-adjusted odds ratio for all-cause mortality of 2.14 (95% CI 1.15–3.99).[146]

Young women find the diagnosis of primary ovarian insufficiency particularly traumatic and frequently need extensive emotional and psychological support. Although most of these women will, in fact, be infertile, it is important to emphasize that primary ovarian insufficiency can be transient and that spontaneous pregnancies have occurred even years after diagnosis.

TREATMENT

9 Results from randomized trials of hormone therapy in postmenopausal women cannot be extrapolated to premenopausal women with ovarian dysfunction. Postmenopausal women who take hormone therapy prolong their exposure to estrogen beyond the average age of completion of their reproductive phase. In contrast, women with primary ovarian insufficiency need exogenous sex steroids to compensate for the decreased production by their ovaries. Importantly, 47% of young women with primary ovarian insufficiency have significantly reduced BMD within 1.5 years of their diagnosis despite taking standard hormone therapy.[143]

DESIRED OUTCOME

The goal of therapy in young women with primary ovarian insufficiency is to provide a hormone replacement regimen that maintains sex steroid status as effectively as the normal, functioning ovary.

GENERAL APPROACH TO TREATMENT

Hormone therapy with estrogen, progestogen, and testosterone is used and generally should be continued until the average age of natural menopause.

PHARMACOLOGIC THERAPY

Optimal hormone therapy depends on whether the patient has primary or secondary amenorrhea. Young women with primary amenorrhea in whom secondary sex characteristics have failed to develop initially should be given very low doses of estrogen in an attempt to mimic the gradual pubertal maturation process. A typical regimen is 0.3 mg CEE unopposed (i.e., no progestogen) daily for 6 months, with incremental dose increases at 6-month intervals until the required maintenance dose is achieved. Gradual dose escalation often results in optimal breast development and allows time for the young woman to adjust psychologically to her physical maturation. Cyclic progestogen therapy, given 12 to 14 days per month, should be instituted toward the end of the second year of treatment.

Women with secondary amenorrhea who have been estrogen deficient for 12 months or longer also should be given low-dose estrogen replacement initially to avoid adverse effects such as mastalgia and nausea. However, the dose can be titrated up to maintenance levels over a 6-month period, and progestogen therapy can be instituted with the initiation of estrogen therapy. Women with a brief history of secondary amenorrhea are less likely to experience undesired effects from hormone therapy if they are given a reduced dose for the first month of therapy, followed by a full dose from the second month onward.

An estrogen dose equivalent to at least 1.25 mg CEE (or 100 mcg transdermal estradiol) is needed to achieve adequate estrogen replacement in young women. A progestogen should be given for 12 to 14 days per calendar month to prevent endometrial hyperplasia (Table 91–9). Estrogens given in usual replacement doses do not suppress spontaneous follicular activity or ovulation. Because women with primary ovarian insufficiency can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns (i.e., only cyclic regimens should be used). Patients who miss an expected menses should be tested for pregnancy and should discontinue hormone therapy. Because most young women negatively associate hormone therapy with menopause in older women, some clinicians prefer to prescribe oral contraceptives for hormone replacement in premenopausal women with hypogonadism. However, oral contraceptives may not inhibit ovulation or effectively prevent pregnancy in young women with elevated gonadotropin levels.

TABLE 91-9 Premenopausal Hormone Replacement Therapy for Young Women with Primary Ovarian Insufficiency

Regimen	Dose	Frequency	Route
Estrogen therapy			
Conjugated equine estrogen	1.25 mg	Daily	Oral
Estropipate (piperazine estrone sulfate)	2.5 mg	Daily	Oral
Micronized 17β-estradiol	4 mg	Daily	Oral
Transdermal estrogen system	100 mcg/24 h	Once or twice weekly	Transdermal patch
Progestogen therapy			
Medroxyprogesterone acetate	10 mg	12–14 days[a]	Oral
Dydrogesterone[b]	20 mg	12–14 days[a]	Oral
Norethindrone acetate	10 mg	12–14 days[a]	Oral
Norethindrone (norethisterone)[b]	1 mg	12–14 days[a]	Oral
Micronized progesterone	200 mg	12–14 days[a]	Oral
Transdermal norethindrone[c]	250 mcg/24 h	Twice weekly for 14 days per calendar month	Transdermal patch

[a]Per calendar month.
[b]In the United States, available in a progestogen-only oral dosage form as 0.35 mg tablets approved for prevention of pregnancy.
[c]Available only in combination with estradiol.

Women with primary ovarian insufficiency have testosterone deficiency.[147] In these young women, testosterone replacement, in addition to estrogen, may be important.[118] However, preliminary analysis of a prospective study at the National Institutes of Health suggests that long-term "physiologic" testosterone supplementation (150 mcg/day), in addition to standard hormone replacement, did not significantly improve BMD and sexual function in these young women.[148,149]

Importantly, all women with primary ovarian insufficiency should understand that hormone therapy generally should be continued until the average age of natural menopause and that long-term follow-up is necessary.

Pharmacoeconomic Considerations

Depending on the duration of therapy, the cost of therapy for primary ovarian insufficiency may be more or less than that associated with therapy for menopausal symptoms. The cost of therapy can be substantial for women who undergo fertility testing and treatment prior to receiving the diagnosis of primary ovarian insufficiency.

EVALUATION OF THERAPEUTIC OUTCOMES

Similar to the treatment of menopause, an assessment of the efficacy of hormone therapy, and its accompanying risks, should be performed on a regular basis. Young women with primary ovarian insufficiency should be monitored annually for their response to treatment, and their adherence with hormone therapy should be assessed regularly. Patients should be evaluated continuously for the presence of signs and symptoms of associated autoimmune endocrine disorders, such as hypothyroidism, adrenal insufficiency, and diabetes mellitus. Baseline BMD testing should be performed in all women with primary ovarian insufficiency. Mammography should be performed annually after age 40 years in accordance with accepted guidelines. Additional mammography screening in premenopausal women younger than 40 years who are receiving physiologic hormone therapy is not warranted. Other tests should be performed as clinically indicated.

CONCLUSIONS

Approximately 1% of women spontaneously develop ovarian insufficiency before age 40 years. Primary ovarian insufficiency is not an early natural menopause. Most affected women produce estrogen intermittently and may ovulate despite the presence of high gonadotropin concentrations. However, these women sustain sex steroid deficiency for more years than do naturally menopausal women, resulting in a significantly higher risk for osteoporosis and cardiovascular disease.

Women with primary ovarian insufficiency need exogenous sex steroids to compensate for the decreased production by their ovaries. Thus, premenopausal hormone therapy is required at least until these women reach the age of natural menopause.

The goal of therapy is to provide a hormone replacement regimen that maintains sex steroid status as effectively as the normal, functioning ovary. This usually requires the administration of estrogen at a dose greater than the standard dose given to older women experiencing natural menopause.

Because women with primary ovarian insufficiency can have spontaneous pregnancies, hormone therapy should produce regular, predictable menstrual flow patterns. Patients who miss an expected menses should be tested for pregnancy and, if positive, the hormone therapy should be promptly discontinued.

Annual follow-up should include assessment of adherence with the prescribed hormone therapy regimen and evaluation for signs and symptoms of associated endocrine disorders.

SECTION 10
UROLOGIC DISORDERS

CHAPTER 92

Erectile Dysfunction

MARY LEE

KEY CONCEPTS

1. The incidence of erectile dysfunction is low in men younger than 40 years of age. The incidence increases as men age, likely as a result of concurrent medical conditions that impair the vascular, neurologic, psychogenic, and hormonal systems necessary for a normal penile erection.
2. Many commonly used drugs have sympatholytic, anticholinergic, sedative, or antiandrogenic effects that may exacerbate or contribute to the development of erectile dysfunction. Clinicians should be familiar with these agents and be prepared to make adjustments in drug regimens to minimize adverse effects of these drugs on a patient's erectile function.
3. The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse the underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, and chronic ethanol abuse, should be addressed and minimized.
4. Specific treatments for erectile dysfunction include vacuum erection devices, pharmacologic treatments, psychotherapy, and surgery.
5. The ideal treatment of erectile dysfunction should have a fast onset, be effective, be convenient to administer, be cost effective, have a low incidence of serious adverse effects, and be free of serious drug interactions.
6. Specific treatment is first initiated with the least invasive forms of treatment, including vacuum erection devices or oral phosphodiesterase inhibitors, followed by intracavernosal injections or intraurethral inserts, and finally by surgical insertion of a penile prosthesis.
7. Vacuum erection devices can have a slow onset of action (30 minutes) and are not discreet; therefore, they are most effective for a couple in a stable relationship.
8. Although phosphodiesterase inhibitors are convenient and effective regardless of the etiology of erectile dysfunction, they fail in 30% to 40% of patients. Also, phosphodiesterase inhibitors are contraindicated in patients taking any dosage formulation of nitrate.
9. Testosterone supplementation should be reserved for patients with primary or secondary hypogonadism who have erectile dysfunction as a consequence of a decreased libido. Testosterone supplementation should not be used by patients with erectile dysfunction who have normal serum testosterone levels.
10. Although intracavernosal injections and intraurethral pellets of alprostadil are effective independent of the etiology of erectile dysfunction, they fail in one third of patients. To self-administer medication by these routes, patients require training to minimize administration-related adverse effects.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The National Institutes of Health Consensus Development Panel on Impotence defines erectile dysfunction as the failure to achieve a penile erection to allow for satisfactory sexual intercourse.[1] Patients may refer to it as impotence.

Erectile dysfunction must be distinguished from disorders of libido, ejaculatory disorders, and infertility, which are caused by different pathophysiologic mechanisms and are treated with alternative agents (Table 92–1). A patient may suffer from one or more disorders of sexual dysfunction. For example, an elderly man with primary hypogonadism may suffer from decreased libido and erectile dysfunction. Diagnosis of the type of sexual disorder that a patient has is a key to initiating the most appropriate treatment.

EPIDEMIOLOGY

1 The incidence of erectile dysfunction is low in men younger than 40 years of age but increases as men age.[2–4] The Massachusetts Male Aging Study, a cross-sectional survey of a random sample of 1,290 men in the Boston area, was conducted during the period

TABLE 92-1 Types of Sexual Dysfunction in Men

Type of Dysfunction	Definition
Decreased libido	Decreased sexual drive or desire
Increased libido	Precocious puberty; inappropriate and excessive sexual drive or desire
Erectile dysfunction (impotence)	Failure to achieve a penile erection suitable for satisfactory sexual intercourse
Delayed ejaculation	Commonly referred to as "dry sex"; ejaculation is delayed or absent
Retrograde ejaculation	Ejaculate passes retrograde into the bladder, instead of toward the anterior urethra (antegrade) and out of the penis
Infertility	Sperm are insufficient in number, have abnormal morphology, or have inadequate motility, and fail to fertilize the ovum

from 1987 to 1989. The study reported an overall prevalence of 52% for any degree of erectile dysfunction in men aged 40 to 70 years, with an age-related increase in incidence ranging from 12.4% in men aged 40 to 49 years, up to 46.4% in men aged 60 to 69 years.[1,2] In the more recent Health Professional Follow-Up Study of more than 31,000 male health professionals aged 53 to 90 years, the prevalence of erectile dysfunction was 33%.[3] Interestingly, although the prevalence of erectile dysfunction increases with patient age, many patients fail to seek medical treatment.[4]

Erectile dysfunction is sometimes assumed to be a symptom of the aging process in men. However, more likely it results from concurrent medical conditions of the patient (e.g., hypertension, arteriosclerosis, hyperlipidemia, diabetes mellitus, or psychiatric disorders) or from medications that patients may be taking for these diseases.[2–5] For example, up to 50% of patients with diabetes mellitus develop erectile dysfunction, and medications such as β-blockers are associated with a high incidence of erectile dysfunction.

PHYSIOLOGY OF A NORMAL PENILE ERECTION

A normal penile erection requires full functioning of several physiologic systems: vascular, nervous, and hormonal. The patient also must be psychologically receptive to sexual stimuli.

VASCULAR SYSTEM

The penis comprises two corpora cavernosa on the dorsal side and one corpus spongiosum on the ventral side. The corpus spongiosum surrounds the urethra and forms the glans penis. The corpora are composed of multiple interconnected sinuses, which can fill with blood to produce an erection. The corpora cavernosa are encased by the tunica albuginea, a fibrous tissue membrane, which has limited distensibility. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, which causes penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules against the tunica albuginea by the swollen corpora (Fig. 92–1).

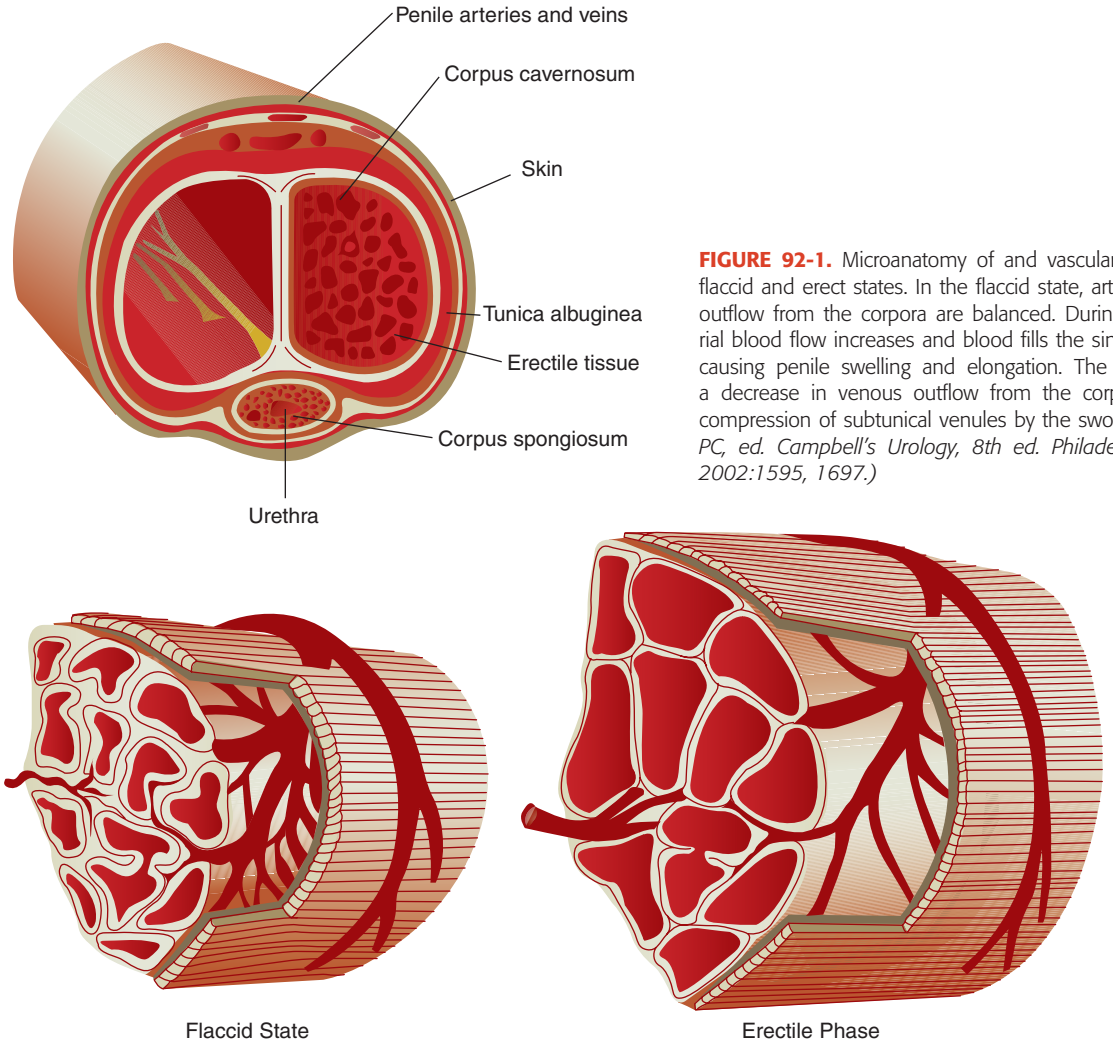

FIGURE 92-1. Microanatomy of and vascular changes in the penis in flaccid and erect states. In the flaccid state, arterial flow into and venous outflow from the corpora are balanced. During the erectile phase, arterial blood flow increases and blood fills the sinusoids within the corpora, causing penile swelling and elongation. The erection is prolonged by a decrease in venous outflow from the corpora, which is caused by compression of subtunical venules by the swollen corpora. *(From Walsh PC, ed. Campbell's Urology, 8th ed. Philadelphia, PA: WB Saunders, 2002:1595, 1697.)*

Arterial flow into the corpora is enhanced by acetylcholine-mediated vasodilation. Acetylcholine indirectly enhances arterial flow to the corpora and increases sinusoidal filling of the corporal tissue. That is, acetylcholine is a coneurotransmitter, which works along with other nonpeptidinergic intracellular neurotransmitters—including cyclic guanosine monophosphate (cGMP), cyclic adenosine monophosphate (cAMP), or vasoactive intestinal polypeptide—to produce vasodilation. In effect, cGMP and cAMP are secondary messengers that direct desired effects in target tissues.[6]

Acetylcholine produces an erection probably through two different pathways. Through one pathway, in the presence of sexual stimulation to genital tissue, acetylcholine enhances the production of nitric oxide by endothelial cells and nonadrenergic–noncholinergic neurons. Nitric oxide enhances the activity of guanylate cyclase, which increases the conversion of cyclic guanosine triphosphate to cGMP. cGMP decreases intracellular calcium concentrations in smooth muscle cells of penile arteries and cavernosal sinuses. As a result, smooth muscle relaxation occurs, which enhances arterial blood flow to and blood filling of the corpora.[5] An erection results.

In an alternative pathway, acetylcholine or prostaglandin E enhances the activity of adenyl cyclase, which increases the conversion of cyclic adenosine triphosphate to cAMP, a potent muscle relaxant. Similar to cGMP, cAMP decreases intracellular calcium concentrations to produce smooth muscle relaxation in cells of the arteries and cavernosal sinuses. Arterial blood flow to and blood filling of the corpora are enhanced, and a penile erection results.[5]

NERVOUS SYSTEM AND PSYCHOGENIC STIMULI

Some erections are mediated by a sacral nerve reflex arc (e.g., erections can occur while the patient is sleeping). However, in the conscious patient, sensory sexual stimulation mediates erections via the central nervous system. That is, when a patient sees an attractive partner, hears sweet words, smells a particular scent, or tastes or touches a pleasant object, these situations can result in an erection. In this case, the patient's brain processes this information and the nervous impulse is carried down the spinal cord to peripheral cholinergic nerves that innervate the vascular supply to the corpora, resulting in an erection.

The medial preoptic area of the hypothalamus is thought to be that portion of the brain responsible for integrating external stimuli. Here dopamine exerts a proerectogenic effect, whereas, α_2-adrenergic stimulation causes the penis to become and/or remain flaccid. After moving down the spinal cord, nerve impulses travel to the penis by efferent peripheral nerves, including inhibitory sympathetic neurons (T11–L2), proerectogenic parasympathetic neurons (S2–S4), and proerectogenic somatic neurons (S2–S4).

In summary, acetylcholine produces an erection by working along with other coneurotransmitters, including cGMP and cAMP. Thus, an erection is mediated neurologically, maintained by arterial blood filling of the corpora, and sustained by occlusion of venous outflow from the corpora.

Detumescence, or the progression of an erect penis to a flaccid state, results from the actions of norepinephrine, which contracts vascular smooth muscle to decrease arterial inflow to the corpora and contracts sinusoidal tissue in the corpora. As a result, venous outflow from the corpora increases.

HORMONAL SYSTEM

Testosterone is principally produced by the testes at a daily rate of 4 to 8 mg. Production follows a circadian pattern with highest blood levels in the morning and lowest levels in the evening. Physiologically active (free) testosterone comprises only 2% of circulating blood levels. About 50% to 60% of testosterone in the bloodstream is tightly bound to sex hormone-binding globulin and is inactive. The rest of circulating testosterone is reversibly bound to albumin; this portion of testosterone is in equilibrium with the free fraction.

Testosterone stimulates libido (sexual drive) and increases muscle mass in males. In some target cells with 5-alpha reductase, testosterone is activated to dihydrotestosterone. Dihydrotestosterone, which is more potent than testosterone, stimulates prostate gland growth, increases facial and body hair, induces baldness, and causes acne. In adipose tissue, a small portion of testosterone is converted to estradiol which can lead to gynecomastia.

Beginning at age 40 years, men experience a gradual decrease in testicular production of testosterone, with an associated decrease in muscle mass and sexual function.[7] The Massachusetts Male Aging Study reported that 6% to 12% of elderly males had symptoms of hypogonadism.[8]

Within the normal physiologic serum total testosterone concentration range (normal, 300–1,100 ng/dL; 10.4–38.2 nmol/L), sexual drive is usually normal. However, because of variability in circulating levels of sex hormone binding globulin, a patient's serum concentration of testosterone should always be interpreted in the context of the patient's symptoms and physical exam findings. To confirm hypogonadism when the serum total testosterone concentration is equivocal, the clinician should obtain a serum free (bioavailable) testosterone level.

The relationship between erectile dysfunction and serum testosterone levels is complicated. Patients with normal serum testosterone levels may have erectile dysfunction, and patients with subnormal serum testosterone levels may have normal sexual function.[5] When a patient has hypogonadism and libido is decreased, a patient may not develop erections. In this case, erectile dysfunction is considered secondary to a decreased libido.

PATHOPHYSIOLOGY

Erectile dysfunction can result from any single abnormality or combination of abnormalities of the four systems necessary for a normal penile erection. Vascular, neurologic, or hormonal etiologies of erectile dysfunction are collectively referred to as *organic erectile dysfunction*. Approximately 80% of patients with erectile dysfunction have the organic type. Patients who do not respond to psychogenic stimuli have *psychogenic erectile dysfunction*.

Diseases that compromise vascular flow to the corpora cavernosum (e.g., peripheral vascular disease, arteriosclerosis, and essential hypertension) are associated with an increased incidence of erectile dysfunction. Diseases that impair nerve conduction to the brain (e.g., spinal cord injury or stroke) or conditions that impair peripheral nerve conduction to the penile vasculature (e.g., diabetes mellitus) can result in erectile dysfunction.

Diseases associated with hypogonadism, primary or secondary, result in subphysiologic levels of testosterone, which cause diminished sexual drive (decreased libido) and secondary erectile dysfunction. Primary hypogonadism can be associated with the normal aging process in men or surgical removal of the testes for treatment of prostate or testicular cancer. Secondary hypogonadism may result from hypothalamic or pituitary disorders of luteinizing hormone–releasing hormone or luteinizing hormone, respectively; or elevated prolactin levels, which can result from pituitary tumors or can occur in patients with chronic renal failure.

Patients must be in the proper mental frame of mind to be receptive to sexual stimuli. Patients who suffer from malaise, have

TABLE 92-2 Medication Classes That Can Cause Erectile Dysfunction

Drug Class	Proposed Mechanism by Which Drug Causes Erectile Dysfunction	Special Notes
Anticholinergic agents (antihistamines, antiparkinsonian agents, tricyclic antidepressants, phenothiazines)	Anticholinergic activity	• Second-generation nonsedating antihistamines (e.g., loratadine, fexofenadine, or cetirizine) are associated with less erectile dysfunction than first-generation agents • Selective serotonin reuptake inhibitor (SSRI) antidepressants cause less erectile dysfunction than tricyclic antidepressants. Of the SSRIs, paroxetine, sertraline, and fluoxetine cause erectile dysfunction more commonly than venlafaxine, nefazodone, trazodone, or mirtazapine. • Phenothiazines with less anticholinergic effect (e.g., chlorpromazine) can be substituted in some patients if erectile dysfunction is a problem
Dopamine antagonists (e.g., metoclopramide, phenothiazines)	Inhibit prolactin inhibitory factor, thereby increasing prolactin levels	• Increased prolactin levels inhibit testicular testosterone production; depressed libido results
Estrogens, antiandrogens (e.g., luteinizing hormone–releasing hormone superagonists, digoxin, spironolactone, ketoconazole, cimetidine)	Suppress testosterone-mediated stimulation of libido	• In the face of a decreased libido, a secondary erectile dysfunction develops because of diminished sexual drive
Central nervous system depressants (e.g., barbiturates, narcotics, benzodiazepines, short-term use of large doses of alcohol, anticonvulsants)	Suppress perception of psychogenic stimuli	
Agents that decrease penile blood flow (e.g., diuretics, peripheral β-adrenergic antagonists, or central sympatholytics [methyldopa, clonidine, guanethidine])	Reduce arteriolar flow to corpora	• Any diuretic that produces a significant decrease in intravascular volume can decrease penile arteriolar flow • Safer antihypertensives include angiotensin-converting enzyme inhibitors, postsynaptic α_1-adrenergic antagonists (terazosin, doxazosin), calcium channel blockers, and angiotensin II receptor antagonists
Miscellaneous • Finsteride, dutasteride • Lithium carbonate • Gemfibrozil • Interferon • Clofibrate • Monoamine oxidase inhibitors	Unknown mechanism	

From Thomas et al.[9] and Lee and Sharifi.[10]

reactive depression or performance anxiety, are sedated, have Alzheimer disease, have hypothyroidism, or have mental disorders, commonly complain of erectile dysfunction. In most studies, patients with psychogenic erectile dysfunction generally exhibit a higher response rate to various interventions than do patients with organic erectile dysfunction because the former have less severe disease.

Social habits of patients have been linked to erectile dysfunction. The vasoconstrictor effect of cigarette smoking may compromise blood flow to the corpora and decrease cavernosal filling. Excessive ethanol intake may lead to androgen deficiency, peripheral neuropathy, or chronic liver disease, all of which can contribute to erectile dysfunction.

2 Medications may cause erectile dysfunction through similar pathophysiologic mechanisms (Table 92–2).[9–11] Medications are estimated to be responsible for approximately 10% to 25% of cases of erectile dysfunction.

CLINICAL PRESENTATION: ERECTILE DYSFUNCTION

General

- Men are affected emotionally in many different ways
- Depression
- Performance anxiety
- Marital difficulties and avoidance of sexual intimacy (patients are often brought to a physician by their partners)
- Nonadherence to medications patient believes are causing erectile dysfunction

Symptoms

- Erectile dysfunction or inability to have sexual intercourse

Signs

- If completing an International Index of Erectile Dysfunction survey, results are consistent with low satisfaction with the quality of erectile function.
- Medical history may identify concurrent medical illnesses, past surgical procedures that interfere with good vascular flow to the penis or damage nerve function to the corpora, or mental disorders associated with decreased reception of sexual stimuli.
- Medication history may reveal prescription or nonprescription medications that could cause erectile dysfunction.
- Physical examination may reveal signs of hypogonadism (e.g., gynecomastia, small testicles, decreased body hair or beard, decreased muscle mass), which may contribute to erectile dysfunction. The patient may have an abnormally curved penis when erect, decreased pulses in the pelvic region (suggesting impaired vascular flow to the penis), or decreased anal sphincter tone (suggesting impaired nerve function to the corpora). Men older than 50 years should undergo a digital rectal examination to determine whether an enlarged prostate is contributing to the patient's erectile dysfunction.

Laboratory Tests

- If patient has signs of hypogonadism and complains of decreased libido, a serum testosterone concentration may be

below the normal range, which would be consistent with a hormonal cause of erectile dysfunction.

- If the patient has an enlarged prostate noted on digital rectal examination, a blood sample for prostate specific antigen should be obtained. If elevated, the patient should be evaluated for a prostate disorder, which could contribute to erectile dysfunction.

DIAGNOSIS

With the availability in the late 1990s of effective medications for erectile dysfunction independent of the etiology, diagnostic evaluation of erectile dysfunction became streamlined.[5,12] Key assessments include a description of the severity of erectile dysfunction, complete medical and surgical histories, review of concurrent medications, physical examination, and selected clinical laboratory tests.[12]

To assess the severity of erectile dysfunction, the patient should be asked about the quality of sexual intercourse for the last 4 weeks to 6 months. A self-administered standardized questionnaire, such as the International Index of Erectile Dysfunction (IIEF), is often used. It is administered before initiation of any treatment and repeated at regular intervals during treatment. It includes 15 questions about the quality of erectile function and satisfactoriness of sexual intercourse.[13] Questions include the following: How often were you able to maintain an erection? How difficult was it to sustain an erection? How satisfied are you with your sexual life? The physician should carefully assess the expectations for erectile function of the patient and the partner to ensure that expectations are reasonable. Shorter versions of the IIEF and other self-reporting questionnaires are also used in clinical practice.

A medical history should be obtained to identify concurrent medical illnesses (e.g., hypertension, atherosclerosis, hyperlipidemia, diabetes mellitus, depression) or surgical procedures (e.g., perineal or pelvic) that are risk factors for or are associated with organic or psychogenic erectile dysfunction. Underlying diseases that do not optimally respond to treatment should be addressed before specific treatment for erectile dysfunction is initiated. If the patient smokes cigarettes, drinks excessive amounts of ethanol, or uses recreational drugs, these social habits should be discontinued before specific treatment for erectile dysfunction is started.

A complete listing of the patient's prescription and nonprescription medications and dietary supplements should be reviewed by the clinician, who should identify drugs that may be contributing to erectile dysfunction. If possible, causative agents should be discontinued or the dose should be reduced.

A physical examination of the patient should include a check for hypogonadism (i.e., signs of gynecomastia, small testicles, and decreased beard or body hair). The penis should be evaluated for diseases associated with abnormal penile curvature (e.g., Peyronie disease), which are associated with erectile dysfunction. Femoral and lower extremity pulses should be assessed to provide an indication of vascular supply to the genitals. Anal sphincter tone and other genital reflexes should be checked for the integrity of the nerve supply to the penis. A digital rectal examination in patients 50 years or older is needed to rule out benign prostatic hyperplasia, which may contribute to erectile dysfunction.

Selected laboratory tests should be obtained to identify the presence of underlying diseases that could cause erectile dysfunction. They include a fasting serum blood glucose and lipid profile. Serum testosterone levels should be checked in patients older than 50 years and in younger patients who complain of decreased libido. At least two serial early morning serum testosterone levels are needed to confirm the presence of hypogonadism.[14,15]

Finally, erectile dysfunction is a potential marker for arteriosclerosis. Therefore, patients who present with erectile dysfunction should undergo a cardiovascular risk assessment to identify treatable medical conditions.[16,17]

TREATMENT

Erectile Dysfunction

DESIRED OUTCOMES

The goal of treatment is improvement in the quantity and quality of penile erections suitable for satisfactory intercourse. Simple as this may sound, healthcare providers must ensure that patients and their partners have reasonable expectations for any therapies that are initiated. Furthermore, only patients with erectile dysfunction should be treated. Patients who have normal sexual function should not seek—or be encouraged to seek—treatment in an effort to enhance sexual function or enable increased activity.[18]

GENERAL APPROACH TO TREATMENT

3 The Second Princeton Consensus Conference is a widely accepted multidisciplinary approach to managing erectile dysfunction that maps out a stepwise treatment plan.[19–21] The first step in clinical management of erectile dysfunction is to identify and, if possible, reverse underlying causes. Risk factors for erectile dysfunction, including hypertension, diabetes mellitus, smoking, or chronic ethanol abuse, should be addressed and minimized. Patients should follow a heart-healthy lifestyle, which includes physical fitness, weight loss to achieve a normal body mass index, low cholesterol diets, no excessive ethanol intake, and no smoking.[22,23] In some cases, these types of interventions are sufficient to restore erectile function. However, if erectile dysfunction does not respond to these measures, specific treatment is indicated.

For patients with psychogenic erectile dysfunction, psychotherapy can be used as monotherapy or as an adjunct to specific treatments for the disorder. To enhance the relevance of psychotherapy, both the patient and the partner should be included in the counseling sessions. Treatment should be individualized and should address immediate factors that may be causing performance anxiety or depression. The effectiveness of psychotherapy is generally low, and long-term psychotherapy is often necessary.

4 5 6 Specific treatments of erectile dysfunction include vacuum erection devices (VEDs), pharmacologic treatments, and surgery. The ideal treatment of this disorder should have a fast onset, be effective, be convenient to administer, be cost effective, have a low incidence of serious adverse effects, and be free of serious drug interactions (Table 92–3). Generally, when choosing from among treatment approaches, those that are least invasive are selected first; more invasive therapies are reserved for patients who do not respond to first-line agents.

The American Urological Association Guideline on the Management of Erectile Dysfunction clearly identifies oral phosphodiesterase inhibitors for first-line treatment. Vacuum erection devices, intracavernosal injection of erectogenic agents, or intraurethral prostaglandin inserts are second-line treatments; prescribing of a particular agent for a patient should be individualized. Surgical intervention should be reserved for patients who fail to respond to first- and second-line treatments.[24] A sample algorithm that guides selection of treatment is shown in Figure 92–2.

TABLE 92-3 Dosing Regimens for Selected Drug Treatments for Erectile Dysfunction

Route of Administration	Generic Name (Brand Name)	Dosage Form	Common Dosing Regimen
Oral	Yohimbine (Aphrodyne, Yocon, Yohimex)	5.4-mg tablet or capsule	5.4 mg 3 times per day
	Sildenafil (Viagra)	25-mg, 50-mg, 100-mg tablet	25–100 mg 1 h before intercourse
	Apomorphine (Uprima)[a]	10-mg sublingual tablet, 25-mg tablet and capsule	10–40 mg daily
	Fluoxymesterone (Halotestin)	2-mg, 5-mg, 10-mg, 50-mg tablet	5–20 mg daily
	Trazodone (Desyrel)	100-mg, 150-mg, 300-mg tablet	50–150 mg daily
	Vardenafil (Levitra)	2.5-mg, 5-mg, 10-mg, 20-mg tablet	5–10 mg 1 h before intercourse
	Tadalafil (Cialis)	5-mg, 10-mg, 20-mg tablet	5–20 mg before intercourse or 2.5–5 mg daily
Topical	Testosterone patch (Testoderm)	4 mg/patch, 6 mg/patch	4–6 mg/day; apply to scrotum
	Testosterone patch (Testoderm TTS)	4 mg/patch, 6 mg/patch	4–6 mg/day; apply to arm, buttock, back
	Testosterone patch (Androderm)	2.5 mg/patch	2.5–5 mg/day; apply to arm, back, abdomen, thigh
	Testosterone gel (AndroGel 1%)	5 g/pkt, 10 g/pkt 5 g/activiation	5–10 g/day; apply to shoulders, upper arms, abdomen
Intramuscular	Testosterone cypionate (Depo-Testosterone)	100 mg/mL, 200 mg/mL	200–400 mg every 2–4 wk
	Testosterone enanthate (Delatestryl)	100 mg/mL, 200 mg/mL	200–400 mg every 2–4 wk
Subcutaneous implant	Testosterone (Testopel)	75-mg pellet	150–450 mg every 3–4 mo
Intraurethral	Alprostadil (MUSE)	125-mcg, 250-mcg, 500-mcg, 1,000-mcg pellet	125–1,000 mcg 5–10 min before intercourse
Intracavernosal	Alprostadil (Caverject)	5-mcg, 10-mcg, 20-mcg injection	2.5–60 mcg 5–10 min before intercourse
	Alprostadil (Edex)	5-mcg, 20-mcg, 40-mcg injection	2.5–60 mcg 5–10 min before intercourse
	Papaverine[b]	30 mg/mL injection	Variable, usually used in combination with alprostadil and phentolamine
	Phentolamine[b]	2.5 mg/mL injection	Variable, usually used in combination with alprostadil and papaverine

[a]Not commercially available in the United States as a sublingual formulation; only available in United States as subcutaneous injection that is FDA approved for Parkinson's disease.
[b]Not FDA approved for this use.

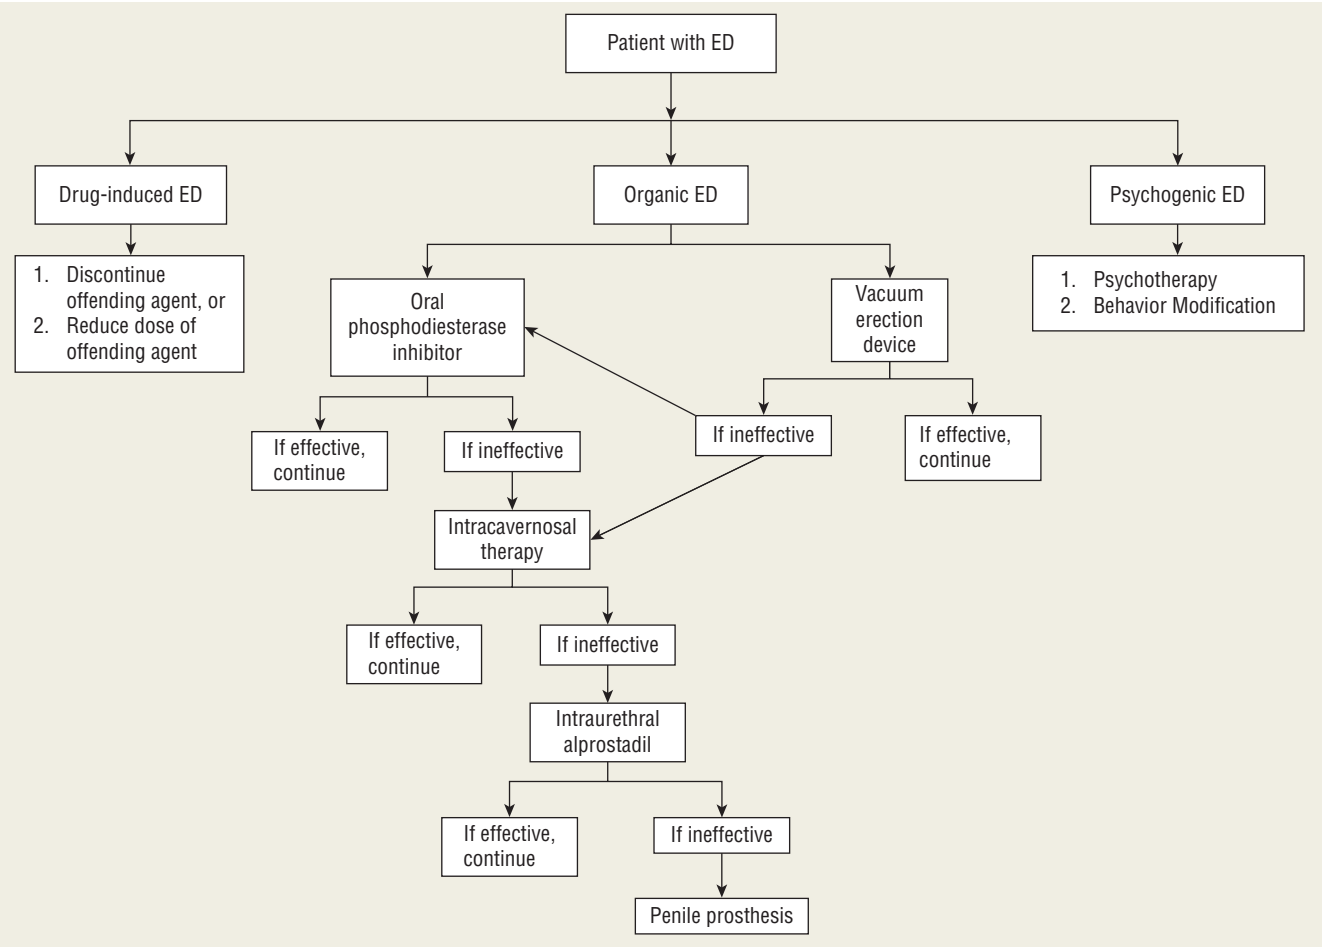

FIGURE 92-2. Algorithm for selecting treatment for erectile dysfunction. For organic erectile dysfunction (ED), oral agents are first-line therapy for younger patients, and vacuum erection devices are generally used first in older patients who are married or otherwise have a stable sexual relationship. These two approaches are sometimes used together in an effort to avoid surgical implantation of penile prostheses.

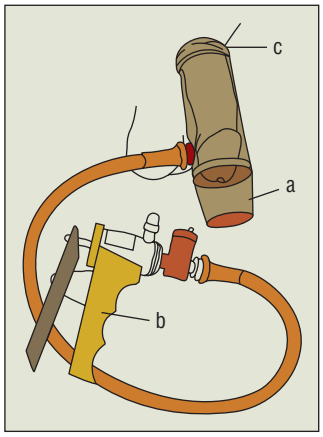

FIGURE 92-3. Technique for using a vacuum erection device with tension band or rubber constriction ring. The patient inserts his penis into the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. The patient activates the pump to produce a vacuum pressure, which draws arteriolar blood into the corpora cavernosa. To prolong the erection, the patient can use constriction bands or tension rings, which are placed at the base of the penis, to keep the arteriolar blood in and reduce venous outflow from the penis. *(From http://kidney.niddk.nih.gov/kudiseases/pubs/impotence.)*

VACUUM ERECTION DEVICE

A VED has three parts: a pump, which generates a negative vacuum pressure; a cylinder, which is closed at one end and into which the penis is inserted; and tubing, which connects the pump to the cylinder. The patient inserts his penis into the open end of the cylinder, which is then pushed up flush against his lower abdomen to create a vacuum chamber. Then the patient activates the pump to produce a vacuum pressure, which draws arteriolar blood into the corpora cavernosa. To prolong the erection, the patient can use constriction bands or tension rings, which are placed at the base of the penis, to keep the arteriolar blood in and to reduce venous outflow from the penis. With the assistance of loading cones to protect the glans, these bands or rings can be rolled over the glans penis and up the erect penile shaft. Alternatively, they can be first threaded onto the plastic cylinder before the penis is inserted. Once the penis is erect, the band or ring can be rolled off the cylinder onto the base of the penis (Fig. 92–3).

7 The onset of action of the VED is comparatively slow (30 minutes), which requires patience from both the patient and the sexual partner. VEDs are not discreet. That is, a patient's use of a VED is evident to the partner. For this reason, VEDs appear to work best in older patients who are married or who have stable sexual relationships. In this group, VEDs could be considered first-line therapy, and the overall satisfaction rate can be as high as 60% to 80%.[5,18] However, 6% to 11% of partners complain that the penis is cool to the touch or is discolored (bluish) in appearance, particularly when constriction bands are used.

VEDs may be used as second-line therapy in patients who do not respond to oral or injectable drug treatments for erectile dysfunction. The combination of a VED with intracavernosal or intraurethral alprostadil is associated with a higher efficacy rate than use of the VED alone. As a result, combination therapy sometimes is attempted before penile prosthesis surgery is considered in the patient who fails VED monotherapy.

VEDs are available with manual or battery-operated pumps. The latter offer greater convenience, particularly in patients with arthritis of the hands, who find manual pumps too difficult and tiring to operate. The American Urological Association recommends the use of commercially available VEDs by prescription only. These have safety mechanisms that minimize the likelihood of excessively high vacuum pressures which can cause penile discomfort and injury.[24]

Pain or injury from VEDs most often is caused by the constriction bands used to sustain an erection. Because these rings trap blood in the corpora and reduce arteriolar flow into the penis, the penile shaft may feel cold and numb. If the constriction bands are applied for longer than 30 to 60 minutes, the penile shaft may turn blue and hurt. Patients may complain that a hinge-like erection is produced in that the penis pivots on the rubber ring or tension band. Patients sometimes fail to ejaculate.

VEDs are contraindicated in patients with sickle cell disease. These patients are prone to priapism, which can be exacerbated by the use of constriction bands with VEDs. The devices also should be used cautiously by patients taking oral anticoagulants because warfarin, through a poorly understood and idiosyncratic mechanism, can cause priapism.

PHOSPHODIESTERASE INHIBITORS

Mechanism

In the presence of sexual stimulation, nitric oxide is released by neurons or endothelial cells in penile tissue, thereby enhancing the activity of guanylate cyclase, the enzyme responsible for conversion of guanylate triphosphate to cGMP (Fig. 92–4).[25] cGMP is a vasodilatory secondary messenger that upregulates the response to nitric oxide, increases smooth muscle relaxation, enhances arterial flow to the corpora cavernosa and enhances blood filling of cavernosal sinuses. Catabolism of cGMP is mediated by phosphodiesterase.

Three competitive, reversible inhibitors of the phosphodiesterase isoenzyme type 5 found in genital tissue are marketed for erectile dysfunction in the United States (Table 92–4). They act by decreasing catabolism of cGMP. However, phosphodiesterase isoenzyme type 5 is also found in peripheral vascular tissue, tracheal smooth muscle, and platelets. Inhibition of phosphodiesterase in these nongenital tissues can produce unwanted effects.

The three marketed phosphodiesterase inhibitors differ in their degree of selectivity in inhibiting other phosphodiesterase isoenzymes, pharmacokinetic profiles, drug–food interactions, and adverse effects (see Table 92–4).

Efficacy

Because of their apparent effectiveness, convenient route of administration, and comparatively low incidence of serious adverse effects, phosphodiesterase inhibitors are considered first-line therapy for erectile dysfunction, particularly in younger patients. They allow for discreet use. Although not based on direct comparison trials, all three commercially available phosphodiesterase inhibitors are considered to be equally effective.[26,27]

In the presence of sexual stimulation and in doses of 25 to 100 mg, sildenafil produces satisfactory erections in 56% to 82% of patients, independent of the etiology of erectile dysfunction. Similar results are documented in the product labeling for the other two agents in this class (65%–80% for vardenafil and 62%–77% for tadalafil). Response rates in the lower range for phosphodiesterase inhibitors have been documented in patients with diabetes mellitus or in patients after radical prostatectomy, probably due to neuropathy or surgery-related nerve damage, respectively.[24,25,28] The effectiveness of the drugs appears to be dose related.

8 Approximately 30% to 40% of patients do not respond to phosphodiesterase inhibitors.[24] At least half of nonresponders can

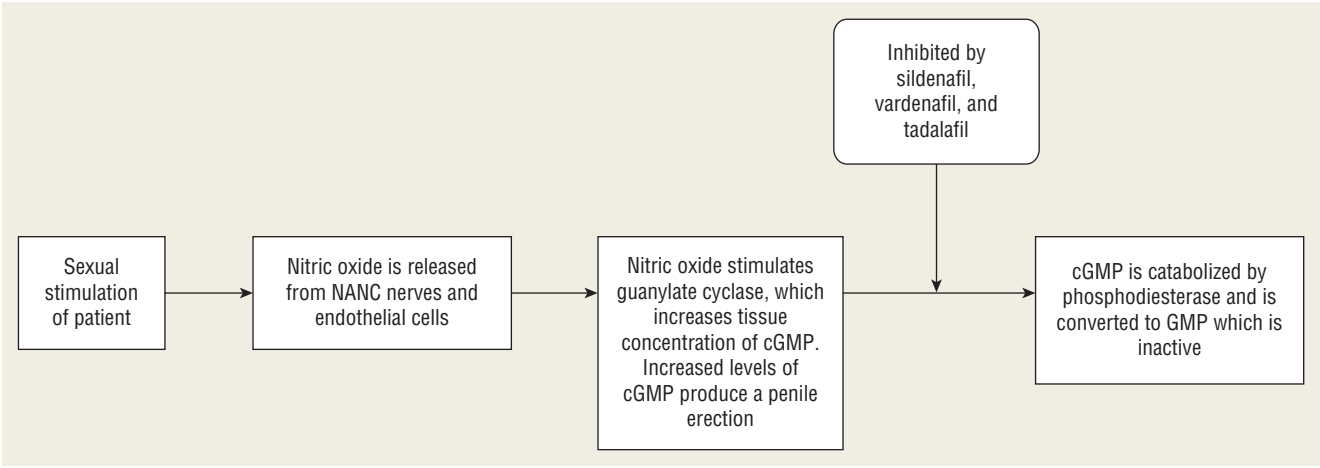

FIGURE 92-4. Mechanism of action of phosphodiesterase inhibitors. All inhibit catabolism of cGMP, a vasodilatory secondary messenger. (cGMP, cyclic guanosine monophosphate; NANC, nonadrenergic noncholinergic.)

benefit from education on proper use of the drugs, and this likely will prove true for the other agents used for erectile dysfunction. Education of patients should include the following points: (1) patients must engage in sexual stimulation (foreplay) for the best response; (2) sildenafil should be taken on an empty stomach, at least 2 hours before meals, for the fastest response, but the other two agents can be taken without regard to meals; (3) taking sildenafil or vardenafil with a fatty meal can decrease the absorption rate, but the absorption rate of tadalafil is not affected;[26] (4) patients who do not respond to the first dose should continue with the phosphodiesterase inhibitor for at least five to eight doses before failure is declared, as increasing success rates are reported with sequential dose administration;[27] (5) some patients require dosage titration up to 100 mg sildenafil, 20 mg vardenafil, or 20 mg tadalafil for a response;[27,28] (6) patients should avoid excessive alcohol intake, which can cause erectile dysfunction; and (7) involvement of the sexual partner can help improve the patient's response to treatment. In addition, treatment of concomitant medical illnesses which contribute to erectile dysfunction (e.g., diabetes mellitus, hypertension, hypogonadism) should be optimized.[20]

The effectiveness of switching from one phosphodiesterase inhibitor to another when the patient does not respond to an initial agent is controversial. In two small studies, vardenafil was beneficial in patients who did not respond to sildenafil.[26,29] However, controlled clinical trials in larger patient groups are needed before this strategy is used as routine treatment.

The phosphodiesterase inhibitors should not be used by patients with normal erectile function. Also, according to Food and Drug Administration (FDA)–approved labeling, the drugs should not be used in combination with other forms of therapy for erectile dysfunction because prolonged erections (which may lead to priapism) may result.[30]

Long-term use of phosphodiesterase inhibitors is not associated with tachyphylaxis.[31,32]

TABLE 92-4 Pharmacodynamics and Pharmacokinetics of Phosphodiesterase Inhibitors

	Sildenafil (Viagra)[a]	Vardenafil (Levitra)[a]	Tadalafil (Cialis)[a]
Inhibits PDE-5	Yes	Yes	Yes
Inhibits PDE-6	Yes	Minimally	No
Inhibits PDE-11	No	No	Yes
Time to peak plasma level (h)	0.5–1	0.7–0.9	2
Fatty meal decreases rate of oral absorption?	Yes	Yes	No
Mean plasma half-life (h)	3.7	4.4–4.8	18
Percentage of dose excreted in feces	80	91–95	61
Percentage of dose excreted in urine	13	2–6	36
Duration (h)	4	4	24–36
Usual dose (mg) before intercourse	25–100	5–20	5–20
Daily dose (mg)	Not applicable	Not applicable	2.5–5
Dose (mg) in patients ≥65 y (mg)	25	5	5–20
Dose (mg) in moderate renal impairment	25–100	5–20	5
Dose (mg) in severe renal impairment	25	5–20	5
Dose (mg) in mild hepatic impairment	25–100	5–20	10
Dose (mg) in moderate hepatic impairment	25–100	5–10	10
Dose (mg) in severe hepatic impairment	25	Not evaluated	Not recommended
Dose in patients taking cytochrome P450 3A4 inhibitors[a]	25 mg	2.5–5 mg every 24–72 h	10 mg every 72 h

[a]Sildenafil doses should be decreased when any potent cytochrome P450 3A4 inhibitor (e.g., cimetidine, erythromycin, clarithromycin, ketoconazole, itraconazole, ritonavir, and saquinavir) is used. Vardenafil doses vary according to the agent used (2.5 mg every 72 hours for ritonavir; 2.5 mg every 24 hours for indinavir, ketoconazole 400 mg daily, and itraconazole 400 mg daily; and 5 mg every 24 hours for ketoconazole 200 mg daily, itraconazole 200 mg daily, and erythromycin). Tadalafil doses are reduced only when the drug is used with the most potent cytochrome P450 3A4 inhibitors (e.g., ketoconazole, ritonavir).
PDE, phosphodiesterase.

SELECTIVITY OF OTHER PHOSPHODIESTERASE ISOENZYMES

More than 25 different phosphodiesterase isoenzymes have been identified; however, the physiologic effects of stimulation and inhibition of some of these isoenzymes remain to be elucidated. Of note, phosphodiesterase isoenzyme type 6 is localized to the rods and cones of the eye. Inhibition of this isoenzyme has been associated with blurred vision and cyanopsia. Sildenafil is the most potent inhibitor of phosphodiesterase isoenzyme type 6, vardenafil is an intermediate inhibitor, and tadalafil is the least potent inhibitor.[26] Likewise, phosphodiesterase isoenzyme type 11 is localized to striated muscle. Inhibition of this isoenzyme has been associated with myalgia and muscle pain. Tadalafil exerts the greatest inhibitory activity against phosphodiesterase type 11.[6]

Pharmacokinetics and Drug–Food Interactions

Pharmacokinetic parameters of the phosphodiesterase inhibitors are listed in Table 92–4.

Vardenafil and sildenafil have similar pharmacokinetic profiles. Both drugs have a 1-hour onset of action and short duration of action. Oral absorption is significantly delayed when either drug is taken within 2 hours of a fatty meal. In contrast, tadalafil has a delayed onset of action of 2 hours, has a prolonged duration of action up to 36 hours, and food does not affect its rate of absorption. Thus, tadalafil offers greater spontaneity for patients, as one dose can last through an entire weekend and allow for multiple acts of sexual intercourse over multiple days with a single dose.[32]

The onset of action of these agents has undergone reexamination to assess how soon after drug administration patients can expect to have an erection suitable for intercourse. Although up to 50% of patients may develop an erection within 20 to 30 minutes of sildenafil 100 mg, vardenafil 20 mg, or tadalafil 20 mg, the rest of the patients may require a full hour to achieve an adequate erectile response.[33] Therefore, patients should be instructed to allow adequate time for the drug to work.

Concomitant ingestion of ethanol with phosphodiesterase inhibitors can result in orthostatic hypotension. Therefore, the manufacturer recommends that patients avoid ethanol when taking these medications.

All three phosphodiesterase inhibitors are hepatically catabolized principally by the cytochrome P450 3A4 microsomal isoenzyme and by other P450 isoenzymes (minor routes) and/or other hepatic enzymes. Sildenafil and vardenafil have active metabolites, which are excreted primarily in the feces (see Table 92–4).

Dosing

The usual oral doses of the phosphodiesterase inhibitors are listed in Table 92–4. Sildenafil and vardenafil should be taken on demand or at least 30 to 60 minutes before sexual intercourse. Tadalafil should be taken at least 2 hours before sexual intercourse. The durations of action for sildenafil and vardenafil are 4 to 5 hours, whereas the effects of tadalafil last for 36 hours. The agents vary as to whether doses must be adjusted for patients 65 years and older and those with compromised hepatic or renal function. Patients should be advised to take no more than the amount prescribed and to use only one dose per day (or less often in the case of some patients taking tadalafil). Doses greater than those recommended have been described in the published literature (e.g., tadalafil 100 mg); however, such dosing regimens have not consistently produced improved erectile responses.

For patients who do not respond to an adequate course of on-demand phosphodiesterase inhibitors for erectile dysfunction, daily low dosing of these agents may improve endothelial function in cavernosal tissue. That is, regular use of phosphodiesterase inhibitors may increase local concentrations of cGMP, which may lead to increased oxygen tension, improved blood flow, and reduced endothelial damage. A preliminary clinical trial of daily use of tadalafil 2.5 or 5 mg showed a 58% frequency of successful sexual intercourse compared with conventional on-demand use of tadalafil 5 to 20 mg, which produced a 21% frequency of success.[34,35] Other potential advantages of daily low dosing regimens include a lower potential for dose-related adverse effects, lower cost, and increased spontaneity of sexual intercourse. However, more extensive clinical study is needed to evaluate the benefit of daily dosing of phosphodiesterase inhibitors before the approach can be preferred to an on-demand regimen.

Adverse Effects

Most adverse effects of the phosphodiesterase inhibitors are mild or moderate and are self-limited, and patients often become tolerant to them with continued use.[36,37] The rates of drug discontinuation caused by adverse effects are low, ranging from 2.1% to 2.5%, and are similar for all three agents. In usual doses the most common adverse effects are headache (11%), facial flushing (12%), dyspepsia (5%), nasal congestion (3.4%), and dizziness (3%),[25] all of which result from vasodilation or smooth muscle relaxation secondary to inhibition of phosphodiesterase isoenzyme type 5 in extragenital tissues.[18]

Sildenafil and vardenafil produce an 8- to 10-mm Hg decrease in systolic and a 5 to 6 mm Hg decrease in diastolic blood pressure starting approximately 1 hour after a dose is taken and lasting for 4 hours. Most patients are asymptomatic as a result of these blood pressure changes, but some patients, particularly those taking multiple antihypertensives or nitrates or those with baseline hypotension, may develop clinical symptoms as a consequence of these peripheral vascular effects. Tadalafil does not produce decreases in blood pressure, but it must be used with caution in patients with cardiovascular disease because of the cardiac risk inherent to sexual activity. A management approach for such patients, developed based on an analysis of deaths in men who were using sildenafil and commonly referred to as the recommendations of the Princeton Consensus Guideline Conference II,[19] should be applied to all the phosphodiesterase inhibitors (Table 92–5).

Sildenafil and vardenafil cause increased sensitivity to light, blurred vision, or loss of blue–green color discrimination in 2% to 3% of patients. These effects result from inhibition of phosphodiesterase type 6 in the photoreceptor cells of in retinal rods and cones, particularly at doses larger than 100 mg. Visual adverse effects commonly occur at the time of peak serum concentrations. Although visual adverse effects are mild and reversible, caution regarding use is recommended for airplane pilots, who rely on green and blue lights for landing planes. Tadalafil has minimal to no inhibitory activity against type 6 phosphodiesterase, and no visual adverse effects have been reported.[38] Nevertheless, according to current product labeling, all phosphodiesterase inhibitors should be used cautiously in patients at risk for retinitis pigmentosa, a genetic disease associated with retinal phosphodiesterase deficiency.

Nonarteritic anterior ischemic optic neuropathy (NAION) is a sudden, unilateral, painless blindness, which may be irreversible. Isolated cases of NAION have been associated with phosphodiesterase inhibitor use.[39] Although a cause-and-effect relationship has not been definitively established, the blood pressure–lowering effects of these medications may decrease blood flow to the optic nerve and lead to sudden unilateral decrease in vision. Because NAION may lead to permanent vision loss, the FDA has required inclusion of warnings on the product labeling of phosphodiesterase inhibitors. Specifically, before receiving these agents, patients at risk

TABLE 92-5 Recommendations of the Second Princeton Consensus Conference for Cardiovascular Risk Stratification of Patients Being Considered for Phosphodiesterase Inhibitor Therapy

Risk Category	Description of Patient's Condition	Management Approach
Low risk	Has asymptomatic cardiovascular disease with < 3 risk factors for cardiovascular disease Has well-controlled hypertension Has mild, stable angina Has mild congestive heart failure (NYHA class I) Has mild valvular heart disease Had a myocardial infarction >6 weeks ago	Patient can be started on phosphodiesterase inhibitor
Intermediate risk	Has ≥3 risk factors for cardiovascular disease Has moderate, stable angina Had a recent myocardial infarction or stroke within the past 6 weeks Has moderate congestive heart failure (NYHA class II)	Patient should undergo complete cardiovascular workup and treadmill stress test to determine tolerance to increased myocardial energy consumption associated with increased sexual activity
High risk	Has unstable or symptomatic angina, despite treatment Has uncontrolled hypertension Has severe congestive heart failure (NYHA class III or IV) Had a recent myocardial infarction or stroke within past 2 weeks Has moderate or severe valvular heart disease Has high-risk cardiac arrhythmias Has obstructive hypertrophic cardiomyopathy	Phosphodiesterase inhibitor is contraindicated; sexual intercourse should be deferred

NYHA, New York Heart Association.
From Kostis et al.[21]

for NAION should be evaluated by an ophthalmologist. Patients at risk include a wide variety of patients: those with glaucoma, macular degeneration, diabetic retinopathy or hypertension, those who have undergone eye surgery or have experienced eye trauma, patients who are age 50 years or more, or smokers. A patient who experiences sudden vision loss while taking a phosphodiesterase inhibitor should be evaluated for NAION before continuing treatment.[40]

Tadalafil produces lower back and limb muscle pain, which occur in a dose-related fashion in 7% to 30% of patients treated with doses of 10 to 100 mg.[41] The mechanism for this is not known. It may be linked to inhibition of type 11 phosphodiesterase, a unique characteristic of tadalafil.

Vardenafil can cause prolongation of the QT interval. Therefore, it should be used cautiously in patients with this anomaly or in patients who are taking medications that prolong the QT interval (e.g., quinidine).

Priapism is a rare adverse effect of phosphodiesterase inhibitors, particularly sildenafil and vardenafil, which have shorter plasma half-lives than tadalafil. Priapism has been associated with excessive doses of the phosphodiesterase inhibitor or concomitant therapy involving other erectogenic drugs.

Drug Interactions

Patients taking organic nitrates may develop severe hypotension if they are taken with phosphodiesterase inhibitors as a result of two major factors: (1) organic nitrates on their own produce hypotension, and (2) organic nitrates are nitric oxide donors, which can stimulate the activity of guanylate cyclase and increase tissue levels of cGMP. For this reason, use of the three phosphodiesterase inhibitors is contraindicated in patients taking nitrates given by any route at scheduled times or intermittently.[19,42] Furthermore, nitrates should be withheld for 24 hours after sildenafil or vardenafil administration and for 48 hours after tadalafil administration.[19,42] Finally, if a patient who has taken a phosphodiesterase inhibitor requires medical treatment of angina, non–nitrate-containing agents (e.g., calcium channel blocker, β-adrenergic antagonist, morphine) should be used.

If severe hypotension occurs after exposure to nitrates and a phosphodiesterase inhibitor, the patient should be placed in a Trendelenburg position and aggressive fluid administration initiated. If severe hypotension continues, parenteral β-adrenergic agonists (e.g., dopamine) should be administered cautiously.

Interestingly, dietary sources of nitrates, nitrites, or L-arginine (a precursor for nitrates) do not interact with the phosphodiesterase inhibitors. This is because dietary sources do not increase circulating levels of nitric oxide in humans.

Sildenafil does not appear to interact with antihypertensive medications. In retrospective analyses of patients taking sildenafil in combination with α-adrenergic antagonists, β-adrenergic antagonists, diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, or calcium channel blockers, the incidence of hypotension was similar to that reported in patients taking sildenafil alone.[43,44] This finding was confirmed by a retrospective analysis of pooled data on more than 4,800 patients in 35 clinical trials.[30]

Small decreases in blood pressure with clinically symptomatic hypotension have been described in some patients taking sildenafil and tadalafil and immediate-release formulations of terazosin and doxazosin.[45] In contrast, concurrent administration of extended-release alfuzosin, silodosin, or tamsulosin, which produce lower peak serum concentrations than immediate-release formulations after administration or exhibit α_{1A}-adrenergic selectivity, show minimal or no decrease in blood pressure.[46–48] Package labeling for phosphodiesterase inhibitors include a caution about concomitant use of phosphodiesterase inhibitors and α-adrenergic antagonists.

Hepatic metabolism of all three phosphodiesterase inhibitors can be inhibited by enzyme inhibitors of CYP 3A4, including cimetidine, erythromycin, clarithromycin, ketoconazole, itraconazole, ritonavir, saquinavir, and grapefruit juice.[48–51] Lower starting doses should be used in these patients (see Table 92–4).

CLINICAL CONTROVERSY

Some clinicians believe that tachyphylaxis may develop with continuous use of sildenafil, but others believe that a lack of responsiveness may be due to worsening of underlying diseases that may contribute to the development of erectile dysfunction.[18] Positive treatment response despite continuous use of these agents for up to 6 years suggests that tachyphylaxis does not occur.[26,38]

TABLE 92-6 Comparison of Testosterone Replacement Regimens and Ideal Testosterone Replacement Regimen

	Achieves Serum Testosterone Concentrations in Normal Range?	Produces Normal Circadian Pattern of Serum Testosterone Concentrations?	Produces Normal Pattern of Serum Concentrations of Androgen Metabolites?	Adverse Effects
Oral testosterone	No	No	No	Hyperlipidemia Sodium retention
Oral alkylated androgens	Yes	No	No	Hyperlipidemia Sodium retention Hepatotoxicity
Intramuscular testosterone cypionate or enanthate	Yes	No; produces supraphysiologic serum concentrations for several days after injection	No, excess testosterone is converted to estradiol	Mood swings Gynecomastia Polycythemia Hyperlipidemia
Transdermal nonscrotal skin patch	Yes	Yes, provided the patch is placed at night	Yes	Dermatitis due to permeation enhancers in formulation
Transdermal scrotal skin patch	Yes	Yes provided the patch is applied in the morning	No; 5α-reductase in scrotal skin metabolizes testosterone and increases serum concentrations of dihydrotestosterone	Dermatitis due to permeation enhancers in formulation
Transdermal gel	Yes	Yes	Yes	May be inadvertently transferred to others who rub up against the patient's skin treated area
Testosterone subcutaneous implant	Yes	No	No; produces elevated concentrations of dihydrotestosterone	Pellet may be extruded accidentally, resulting in loss of drug effect

TESTOSTERONE REPLACEMENT REGIMENS

Mechanism

9 Testosterone replacement regimens supply exogenous testosterone and restore serum testosterone levels to the normal range (300–1,100 ng/dL; 10.4–38.2 nmol/L). In so doing, testosterone replacement regimens correct symptoms of hypogonadism, which include malaise, loss of muscle strength, depressed mood, and decreased libido. Testosterone can directly stimulate androgen receptors in the central nervous system and is thought to be responsible for maintaining normal sexual drive. In addition, testosterone may stimulate nitric oxide synthase, thereby increasing cavernosal concentrations of nitric oxide, and enhancing the effects of phosphodiesterase type 5 in cavernosal tissue.[52]

Indications

Testosterone replacement regimens are indicated in symptomatic patients with primary or secondary hypogonadism, as confirmed by both the presence of a decreased libido and low serum concentrations of testosterone.[18] Serum testosterone concentrations typically are measured in the early morning because the secretion pattern of this hormone follows a circadian pattern, with highest serum concentrations in the morning hours. Simultaneous serum luteinizing hormone levels help to distinguish patients with primary hypogonadism, who have elevated luteinizing hormone levels, from those with secondary hypogonadism, who have decreased luteinizing hormone levels. Primary hypogonadism can be a characteristic of aging men who undergo andropause, in which the Leydig cells of the testes slowly and progressively decrease testosterone production.[52] Symptoms, including decreased libido, erectile dysfunction, gynecomastia, decreased muscle mass, increased body fat, and osteopenia, develop gradually over years.

Testosterone replacement regimens should never be administered to men with normal serum testosterone levels.

Efficacy

Testosterone replacement regimens restore muscle strength and sexual drive and improve mood in patients with hypogonadism. Improvements are generally observed within days or weeks of the start of testosterone replacement. Administration of testosterone will correct the serum testosterone level to the normal range. No additional benefit has been demonstrated for large doses of testosterone, which increase the serum testosterone level from the low end to the upper end of the normal range or to the above-normal range.[53] Testosterone replacement regimens do not directly correct erectile dysfunction; instead, they improve libido, thereby correcting secondary erectile dysfunction.[54]

Testosterone replacement regimens can be administered orally, parenterally, or transdermally (Table 92–6). Injectable testosterone replacement regimens are the preferred treatment for symptomatic patients with primary or secondary hypogonadism because they are effective, inexpensive, and not associated with the bioavailability problems or hepatotoxic adverse effects of oral androgens.[52] Although convenient for the patient, testosterone patches and gels are much more expensive than other forms of androgen replacement; therefore, they should be reserved for patients who refuse injectable testosterone.

In the ideal testosterone replacement regimen, the medication would mimic the normal circadian pattern of serum testosterone concentrations such that peak and trough concentrations occur in the early morning and late afternoon, respectively; produce serum concentrations in the normal range; produce serum concentrations of dihydrotestosterone and estradiol, which are metabolites of testosterone that mimic the normal physiologic pattern; and produce minimal adverse effects.[52] Table 92–6 compares commercially available testosterone replacement regimens for these characteristics and shows that an ideal regimen has yet to be identified.

Pharmacokinetics

Natural testosterone has poor oral bioavailability because of extensive first-pass hepatic metabolism; therefore, large doses must be taken. To improve oral bioavailability, alkylated derivatives were formulated. Of these derivatives, methyltestosterone and fluoxymesterone are more resistant to hepatic catabolism and can be taken in smaller daily doses, which are potentially safer. However, oral alkylated derivatives of testosterone are not metabolized to dihydrotestosterone or estradiol, and are associated with a higher incidence of serious hepatotoxicity and therefore are not preferred for management of hypogonadism.

An alternative to oral administration is the testosterone buccal system (Striant), which is applied to the gum above the upper incisor teeth twice per day. Over time it forms a gel from which testosterone is absorbed. One advantage of this route of administration is that the drug bypasses first-pass hepatic catabolism, which allows for increased bioavailability of testosterone.

Several testosterone esters have been formulated for intramuscular injection, with different durations of action (see Table 92–3). The shorter-acting testosterone propionate, which requires dosing 3 times per week, has been replaced with testosterone cypionate or enanthate, which can be dosed every 2, 4, or 6 weeks in most patients. An even longer-acting parenteral testosterone is available as a subcutaneous implant for dosing every 3 to 6 months. Although this schedule minimizes repeat visits to the clinician's office for dosing, the implant must be administered by a physician, and the implanted pellet may be extruded after administration. This extrusion has been reported in up to 8.5% of treated patients and results in loss of drug effect. These testosterone formulations produce supraphysiologic patterns of serum testosterone during the dosing interval, which have been linked to mood swings in some patients.

Topical testosterone replacement regimens can be delivered as once-daily patches or gel. Testosterone patches increase serum testosterone levels into the normal range in 2 to 6 hours. Serum testosterone levels return to baseline 24 hours after patch administration. However, unlike oral or injectable supplements, transdermal testosterone patches applied at bedtime or testosterone gel applied each morning produce physiologic patterns of serum testosterone levels throughout the day. The clinical importance of this biochemical effect is unknown.[52]

The original Testoderm brand patch was formulated for scrotal application. Scrotal skin is thinner and has a richer vascular supply than does the skin on the arms or thighs. Therefore, application of Testoderm patches produces excellent absorption of the hormone. However, the patch can fall off when the scrotum becomes damp or moist, when the patient exercises, or if the scrotum is excessively hairy.

For improved convenience, Androderm and Testoderm TTS patches were formulated for application to the arms, buttocks, or back; Androderm can also be applied to the thighs. The addition of absorption enhancers and different adhesives has been linked to a higher incidence of contact dermatitis with Androderm patches compared with the original Testoderm scrotal patch.[55]

Testosterone gel 1% formulation (AndroGel) is applied in much larger doses (5 or 10 g each day) to the skin of the shoulders, upper arms, or abdomen. The hormone is absorbed quickly, within 30 minutes, but several hours may be required for complete absorption of the dose. For this reason, the patient should be reminded to wait at least 5 to 6 hours after application before showering. To prevent inadvertent transfer of testosterone gel to others, the patient should thoroughly wash his hands with soap and water after administration of a dose, and allow the application site to dry undisturbed for several minutes before dressing or covering it.

Dosing

Table 92–3 lists the usual doses for testosterone replacement regimens. Two to 3 months is considered an adequate treatment trial with a particular dose. Thus, a dose should not be increased until the patient has used one particular dose for at least this time period.[53] The serum testosterone level should return to the normal range and symptoms of androgen deficiency should be relieved with appropriate dosing.

Before initiating any testosterone replacement regimen in patients 40 years and older, patients should be screened for benign prostatic hyperplasia and prostate cancer. Both of these diseases are testosterone-dependent conditions and theoretically could be worsened by exogenous administration of testosterone. Prostate cancer is a contraindication to androgen supplementation. To screen for these conditions, a prostate-specific antigen serum concentration should be obtained and a digital rectal examination of the prostate performed. These tests are generally repeated at 1-year intervals after treatment is started.[52]

Adverse Effects

Testosterone replacement regimens can cause sodium retention, which can cause weight gain, or exacerbate hypertension, congestive heart failure, and edema. Gynecomastia can occur as a result of conversion of testosterone to estrogen in peripheral tissues. This has been reported most often in patients with liver cirrhosis.

Testosterone replacement regimens are contraindicated in patients with breast cancer and untreated prostate cancer.

Although serum lipoprotein perturbations may occur, testosterone replacement regimens have a neutral effect in that they decrease both total cholesterol and high-density lipoprotein cholesterol levels. No cases of cardiovascular disease have been reported with testosterone replacement regimens.

Large doses of parenteral testosterone can produce adverse metabolic effects. Thus, patients on long-term testosterone replacement regimens must undergo clinical laboratory testing for a serum testosterone level and hematocrit before starting treatment and every 6 to 12 months during treatment.[54] Repeated serum testosterone levels that exceed the normal range require a dosage reduction or increased interval between drug doses. If the hematocrit exceeds 55% (0.55), the testosterone replacement regimen should be withheld to avoid polycythemia and its consequences.

Oral alkylated testosterone replacement regimens have caused hepatotoxicity, ranging from mild elevations of hepatic transaminases to serious liver diseases, including peliosis hepatis (hemorrhagic liver cysts), hepatocellular and intrahepatic cholestasis, and benign or malignant tumors. For this reason, parenteral testosterone replacement regimens are preferred.

Topical testosterone patches may cause contact dermatitis, which responds well to topical corticosteroids. This adverse effect has been associated with the presence of permeation enhancers, which are added to patch formulations. If the dermatitis becomes problematic, an alternative is testosterone gel formulations, which are associated with a lower incidence of contact dermatitis compared with patches.

ALPROSTADIL

Mechanism

Alprostadil, also known as prostaglandin E_1, stimulates adenyl cyclase, resulting in increased production of cAMP, a secondary messenger that decreases the intracellular calcium concentration and causes smooth muscle relaxation of the arterial blood vessels and sinusoidal tissues in the corpora. This results in enhanced blood flow to and blood filling of the corpora.

Alprostadil is commercially available as an intracavernosal injection (Caverject and Edex) and as an intraurethral insert (medicated urethral system for erection [MUSE]).

Indications

Both commercially available formulations of alprostadil are FDA approved as monotherapy for management of erectile dysfunction. Alprostadil is more effective by the intracavernosal route than the intraurethral route.

The enhanced efficacy of the intracavernosal injection may be related to the excellent bioavailability of the drug when injected directly into the corpora cavernosum. In contrast, intraurethral alprostadil doses generally are several hundred times larger than intracavernosal doses. This is because intraurethral alprostadil must be absorbed from the urethra, through the corpus spongiosum, and into the corpus cavernosum, where it exerts its full proerectogenic effect.

Although several other agents, including papaverine, phentolamine, and atropine, have been used off-label for intracavernosal therapy, alprostadil is preferentially prescribed. This is because intracavernosal alprostadil has been FDA approved for erectile dysfunction, it does not require extemporaneous compounding, and it has a low potential for causing prolonged erections and priapism.

Both formulations of alprostadil are considered more invasive than VEDs or phosphodiesterase inhibitors. For this reason, intracavernosal alprostadil is generally prescribed after patients do not respond to or cannot use less invasive interventions. Intracavernosal alprostadil is preferred over intraurethral alprostadil because of its greater effectiveness. Intracavernosal alprostadil may be preferred in patients with diabetes mellitus, who are accustomed to injectable drug therapy and may have peripheral neuropathies, which decrease the patient's perception of pain upon injection. Intraurethral alprostadil is generally reserved as a treatment of last resort for patients who do not respond to other less invasive and more effective forms of therapy and who refuse surgery.

Intracavernosal Alprostadil

Efficacy The overall efficacy of intracavernosal alprostadil is 70% to 90%.[5] Three characteristics of intracavernosal alprostadil include the following:

1. The effectiveness of alprostadil is dose related over the range of 2.5 to 20 mcg. The mean duration of erection is directly related to the dose of alprostadil administered and ranges from 12 to 44 minutes.
2. A higher percentage of patients with psychogenic and neurogenic erectile dysfunction respond to alprostadil at a lower dose compared to patients with vasculogenic erectile dysfunction.
3. Tolerance does not appear to develop with continued use of intracavernosal alprostadil at home.

⓾ Although 70% to 75% of patients respond to intracavernosal alprostadil, a high proportion of patients elect to discontinue its use over time. Depending on the study and the length of observation, 30% to 50% of patients voluntarily discontinue therapy, usually during the first 6 to 12 months. Common reasons for discontinuation include lack of perceived effectiveness; inconvenience of administration; an unnatural, nonspontaneous erection; needle phobia; loss of interest; and cost of therapy.[5,56]

Approximately one third of patients do not respond to usual doses of intracavernosal alprostadil. In these patients, intracavernosal alprostadil has been used successfully along with VEDs. Such combination therapy can be attempted by patients before transitioning to more invasive surgical procedures.[57,58] Alternatively, intracavernosal injections of synergistic combinations of vasoactive agents that act by different mechanisms have been used.[57] Intracavernosal drug combinations typically produce an erection that lasts longer than an erection produced by any one of the agents in the mixture. In addition, because of the low dosage of each agent in the combination, fewer systemic and local fibrotic adverse effects develop compared with high-dose monotherapy. For example, when used in low-dose combination regimens, papaverine is less likely to induce hypotension and liver dysfunction, and phentolamine is less likely to induce tachycardia and hypotension.[58] However, as previously mentioned, such intracavernosal drug combinations are not commercially available and must be extemporaneously compounded.

Pharmacokinetics Intracavernosal injection should be administered into only one corpus cavernosum. From this injection site, the drug will reach the other corpus cavernosum through vascular communications between the two corpora. Alprostadil acts rapidly, with an onset of 5 to 15 minutes. The duration is directly related to the dose. Within the usual dosage range of 2.5 to 20 mcg, the duration of erection is no more than 1 hour. Higher doses are expected to exhibit a longer duration of action. Local enzymes in the corpora cavernosum quickly metabolize alprostadil. Any alprostadil that escapes into the systemic circulation is deactivated on first pass through the lungs.[5] Hence, the plasma half-life of alprostadil is approximately 1 minute, and the potential for systemic adverse effects is negligible. Dose modification is not necessary in patients with renal or hepatic disease.

Dosing The usual dose of intracavernosal alprostadil is 10 to 20 mcg, with a maximum recommended dose of 60 mcg. Doses greater than 60 mcg have not produced any greater improvement in penile erection but may cause hypotension or prolonged erections lasting more than 1 hour.[5] The dose should be administered 5 to 10 minutes before intercourse. The manufacturer recommends that patients be slowly titrated up to the minimally effective dosage to minimize the likelihood of hypotension. Under a physician's supervision, patients should be started with a 1.25-mcg dose, which can be increased in increments of 1.25 to 2.50 mcg at 30-minute intervals up to the lowest dose that produces a firm erection for 1 hour and does not produce adverse effects. In clinical practice, this process is rarely done because it is time consuming. Thus, many physicians start the patient on 10 mcg and move quickly up the dosage range to identify the best dose for the patient. To avoid adverse effects, patients should receive no more than one injection per day and not more than three injections per week.

Intracavernosal injections should be performed using a 0.5-inch, 27- or 30-gauge needle. A tuberculin syringe or a syringe prefilled with diluent as supplied by the manufacturer should be used to ensure precise measurement of doses. Patients with needle phobia, poor vision, or poor manual dexterity can use commercially available autoinjectors (e.g., PenInject) to facilitate administration of intracavernosal alprostadil.

Intracavernosal injections require that the patient or the sexual partner practice good aseptic technique (to avoid infection), have good manual skills and visual ability, and be comfortable with injection techniques. When practicing self-injection, the patient should use one hand to firmly hold the glans penis against his thigh to expose the lateral surface of the shaft. The injection should be made at right angles into one of the lateral surfaces of the proximal third of the penis. The injection should never be made into the dorsal or ventral surface of the penis. This will prevent inadvertent injection of the drug into arteries on the dorsal surface or the urethra on the ventral surface. After the injection, the penis should be massaged to help distribute the drug into the opposite corpus cavernosum. Injection sites should be rotated with each dose. Finally, manual pressure should be applied to the injection site for 5 minutes to reduce the likelihood of hematoma formation (Fig. 92–5).

Once the optimal dosage of intracavernosal alprostadil is established, the patient should return for routine medical followup every 3 to 6 months. Some patients subsequently require dosage adjustment, largely attributed to worsening of the underlying disease that is contributing to the erectile dysfunction.

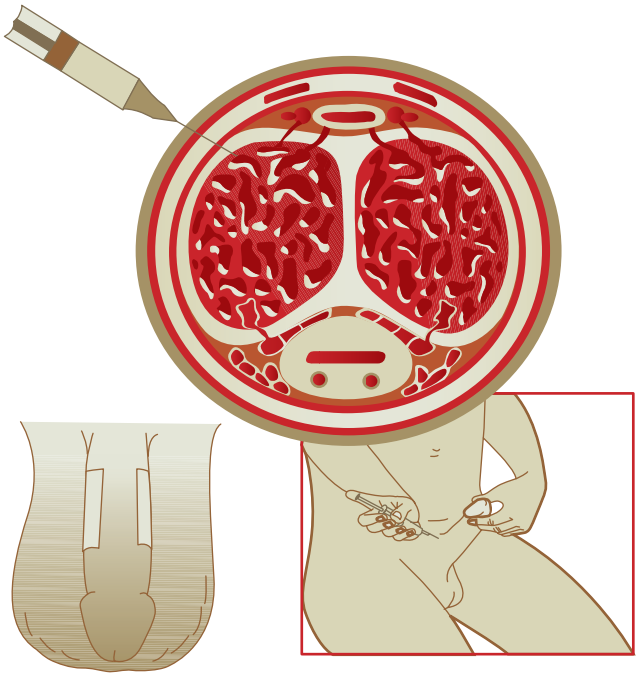

FIGURE 92-5. Technique for administration of intracavernosal injections. *(From Caverject [package insert]. New York, NY: Pfizer Inc; 1999. Data from http://media.pfizer.com/files/products/uspi_caverject_powder.pdf.)*

Adverse Effects Intracavernosal alprostadil is most commonly associated with local adverse effects, which occur most often during the first year of therapy. However, improved administration technique with continued use is believed to account for the lower frequency of adverse effects during subsequent treatment periods.

Intracavernosal injections are associated with several local adverse effects. Cavernosal plaques or areas of fibrosis at injection sites form in approximately 2% to 12% of patients. When they occur, the patient should suspend further injections until the plaques resolve. These plaques may cause penile curvature, similar to Peyronie disease, which makes sexual intercourse difficult or impossible. The cause of corporal fibrosis and plaque formation is unknown. This adverse effect may be caused by poor injection technique or by alprostadil itself. Although patients have developed corporal fibrosis, alprostadil may be less likely to cause this adverse effect compared to other intracavernosal drug combinations, such as phentolamine or papaverine. Unlike cavernosal fibrosis associated with large doses and repeated administration of papaverine, penile scarring secondary to alprostadil appears to be unpredictable.

Alprostadil causes penile pain in approximately 10% to 44% of patients. The pain has been described as a burning discomfort or dull pain near the injection site or during the erection, which generally does not persist after the penis becomes flaccid. The pain usually is mild, generally does not require discontinuation of therapy, and often abates even with continued treatment. However, 2% to 5% of patients discontinue taking alprostadil because of severe pain. The pain can be managed by oral analgesics (e.g., acetaminophen), if necessary. One investigator has recommended adding procaine to intracavernosal alprostadil, but this may mask the signs of more serious adverse effects of the drug or of penile injury during intercourse and is not recommended.[59] The mechanism of this adverse reaction is poorly understood. Alprostadil may intrinsically produce pain. Also, the pain may be a result of the pH of the parenteral solution. Alprostadil is acidic, and the commercially available Caverject formulation is buffered with sodium citrate, a weak base, to reduce pain on injection.

Priapism, a prolonged, painful erection lasting more than 1 hour, occurs in 1% to 15% of treated patients. It occurs most often during the dose titration period and is rare thereafter. Blood sludging in the corpora can lead to tissue hypoxia and cavernosal fibrosis and scarring. The risk for this complication is greatest for erections that persist beyond 4 hours. Patients are advised to seek medical attention immediately when drug-induced erections last more than 1 hour, as this is considered a urologic emergency. Its management includes supportive care, including analgesics for pain and sedatives for anxiety. In addition, needle aspiration of sludged blood in the corpora or intracavernosal injection of α-adrenergic agonists (e.g., phenylephrine) has been used. These procedures facilitate venous drainage of the corpora, allowing venous outflow to "catch up" with arterial inflow.

The likelihood of prolonged erections with intracavernosal alprostadil is dose related. Therefore, to prevent this adverse effect, the lowest effective dose should be used, and the dose should be titrated to ensure that the duration of the erection is no more than 1 hour.

Other local adverse effects include injection site hematomas and bruising. These effects are largely the result of poor injection technique. To minimize the risk of injection site hematomas, patients should be advised to apply pressure to the injection site for 5 minutes after each dose. Similarly, infection at the injection site has been reported. Meticulous aseptic technique is necessary to prevent this complication.

Intracavernosal alprostadil rarely causes systemic adverse effects, owing to the agent's local catabolism in cavernosal tissue and rapid deactivation in pulmonary tissue (if any of the drug escapes into the systemic circulation). However, large doses greater than 20 mcg are associated with dizziness and hypotension in some patients and is one reason why such large doses are not commonly used.

Intracavernosal injection therapy should be used cautiously by patients at risk for priapism, including patients with sickle cell disease or lymphoproliferative disorders. It should be used cautiously by patients who may develop bleeding complications secondary to injections, including patients with thrombocytopenia or those taking anticoagulants. It also should be used cautiously by patients who use poor-quality injection technique, including patients with psychiatric disorders, obese patients (who may not be able to reach or see the penile injection site), patients who are blind, and patients with severe arthritis.

Intraurethral Alprostadil

Efficacy 10 Intraurethral alprostadil inserts are marketed as MUSE, which contains a medication pellet inside a prefilled urethral applicator. Multiple studies show this product has an overall effectiveness rate of 43% to 65%[5] compared with 70% to 90% for intracavernosal alprostadil. Its decreased effectiveness and inconvenient administration method have resulted in this product being considered a third-line treatment option for patients with erectile dysfunction. However, some patients respond to intraurethral alprostadil even though they did not respond to intracavernosal alprostadil.[60]

Intraurethral alprostadil has been combined with an adjustable penile constriction band to improve treatment response.[61]

Pharmacokinetics Following intraurethral instillation, alprostadil is absorbed quickly through the urethra, into the corpus spongiosum, and then into the corpora cavernosum. As much as 90% of each dose is absorbed by the urethra and corpus spongiosum in less than 10 minutes, with peak absorption occurring in 20 to 25 minutes. An estimated 20% of each dose is delivered to the corpora cavernosum. As with intracavernosal injections of alprostadil, any drug absorbed into the systemic circulation is rapidly metabolized on first pass through the lungs.

The onset after intraurethral insertion is similar to that of intracavernosal injection, 5 to 10 minutes.

Dosing The usual dose of intraurethral alprostadil is 125 to 1,000 mcg. The dose should be administered 5 to 10 minutes before sexual intercourse. No more than two doses per day are recommended. Before administration, the patient should be advised to empty his bladder, voiding completely.

Similar to intracavernosal injection treatments, intraurethral insertion of alprostadil requires good manual and visual skills to minimize the risk of urethral injuries. Intraurethral alprostadil is supplied in a prefilled intraurethral applicator. The patient should void first. With one hand the patient holds the glans penis, and with the other hand the patient inserts the intraurethral applicator 0.5 inch (1.3 cm) into the urethra. The drug pellet is then pushed into the urethra. The penis should be massaged to enhance drug dissolution in the urethral fluids and drug absorption (Fig. 92–6).

Adverse Effects The urethra can be injured because of improper administration technique. Injuries can lead to urethral stricture and difficulty voiding. Patients should receive complete education about optimal administration procedures before starting treatment.

Urethral pain has been reported in 24% to 32% of patients. Usually it is mild and does not require discontinuation of treatment. Female sexual partners may experience vaginal burning, itching, or pain, which probably is related to transfer of alprostadil from the man's urethra to the woman's vagina during intercourse.

Prolonged painful erections (priapism) have been rarely reported. Syncope and dizziness have been reported rarely (only 2%–3% of patients) and likely are related to use of excessively large doses.

CLINICAL CONTROVERSY

Although combinations of proerectogenic drugs (e.g., sildenafil plus alprostadil intracavernosal injection) may be used by some patients who do not respond to a single agent, such combinations are not recommended by the FDA and may lead to prolonged erections and priapism.

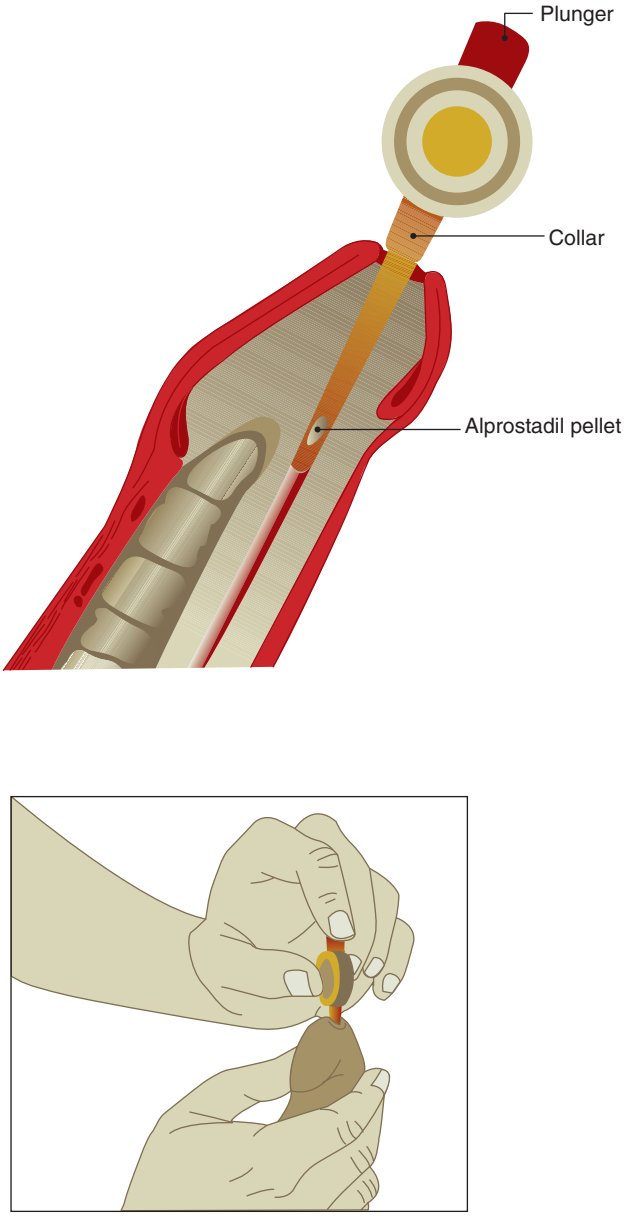

FIGURE 92-6. Technique for administration of intraurethral alprostadil with a medicated urethral system for erection applicator. *(From Muse [package insert]. Mountain View, CA: Vivus, Inc.; 2003. Data from http://www.vivus.com.)*

UNAPPROVED AGENTS

A variety of other commercially available and investigational agents have been used for management of erectile dysfunction. Although it is beyond the scope of this chapter to discuss all of them, some of the more commonly used agents are discussed here.

Trazodone

The mechanism by which trazodone produces an erection is not clear. It likely acts peripherally to antagonize α-adrenergic receptors. As a result, a predominant cholinergic effect results, which causes peripheral arteriolar vasodilation and relaxation of cavernosal tissues, enhancing blood filling of the corpora. Intracavernosal injection of trazodone in experimental studies supports this likely mechanism.[62]

Although some clinical trials suggested that trazodone 50 to 200 mg daily by mouth might be effective in the management of erectile dysfunction, these trials were generally poorly controlled, were nonrandomized, included small samples treated for short time periods, and did not include validated objective parameters of response.[62,63]

The adverse effects of trazodone, when used for erectile dysfunction, are similar to those reported with trazodone when used to treat depression and include dry mouth, sedation, and dizziness.

Yohimbine

Yohimbine, a tree-bark derivative also known as *yohimbe*, is widely used as an aphrodisiac. Yohimbine is a central α_2-adrenergic antagonistic that increases catecholamines and improves mood. Some investigators believe that yohimbine has peripheral proerectogenic effects. Yohimbine may reduce peripheral α-adrenergic tone, thereby permitting a predominant cholinergic tone, which could result in a vasodilatory response.[5,64] The usual oral dose is 5.4 mg 3 times per day.

A controlled clinical trial has shown that high-dose yohimbine (100 mg daily) is no more effective than placebo.[65] Based on a meta-analysis of published studies that came to the same conclusion, the American Urological Association has cautioned against the use of yohimbine.[24] In addition, yohimbine can cause many systemic adverse effects, including anxiety, insomnia, tachycardia, and hypertension.

Papaverine

Papaverine is a nonspecific phosphodiesterase inhibitor that decreases metabolic catabolism of cAMP in cavernosal tissue. As a result of enhanced tissue levels of cAMP, smooth muscle relaxation occurs. Cavernosal sinusoids fill with blood, and a penile erection results.

Papaverine is not FDA approved for erectile dysfunction. Intracavernosal papaverine alone is not commonly used for management of erectile dysfunction because the large doses required produce dose-related adverse effects, such as priapism, corporal fibrosis, hypotension, and hepatotoxicity.[58,66] Papaverine is more often administered in lower doses combined with phentolamine and/or alprostadil. A variety of formulas have been used, but no one mixture has been proven better than other mixtures (see Table 92–6). Combination formulations are considered safer and are associated with the potential for fewer serious adverse effects than high doses of any one of these agents.

A portion of each papaverine dose is systemically absorbed, and its prolonged plasma half-life of 1 hour contributes to adverse effects. The usual dose of papaverine is 7.5 to 60 mg when used as a single agent for intracavernosal injection. When used in combination, the dose decreases to 0.5 to 20 mg.

If treated with papaverine, patients with a history of underlying liver disease or alcohol abuse should undergo liver function testing at baseline and every 6 to 12 months during continued treatment.

Phentolamine

Phentolamine is a competitive nonselective α-adrenergic blocking agent. It reduces peripheral adrenergic tone and enhances cholinergic tone. As a result, it improves cavernosal filling and is proerectogenic.

Phentolamine has most often been administered as an intracavernosal injection. Monotherapy is avoided because large doses are required for an erection, and at these large doses systemic hypotensive adverse effects would be prevalent. Most often, phentolamine has been used in combination with other vasoactive agents for intracavernosal administration. A ratio of 30 mg papaverine to 0.5 to 1 mg phentolamine is typical, and the usual dose ranges from 0.1 to 1 mL of the mixture. Such a mixture promotes local effects of phentolamine and minimizes systemic hypotensive adverse effects.

Hypotension is the most common adverse effect of intracavernosal phentolamine. It is more common and more severe with large doses or in patients with poor injection technique who have injected into a vein (rather than the cavernosa). Prolonged erections have been reported in patients who used excessive doses of intracavernosal medications in combination.

PENILE PROSTHESES

Surgical insertion of a penile prosthesis is the most invasive treatment of erectile dysfunction. It is reserved for patients who do not respond to or who are not candidates for less invasive oral or injectable treatments.

Prosthesis insertion requires anesthesia and skilled urologists. Two prostheses are widely used: malleable and inflatable. Malleable or semirigid prostheses consist of two bendable rods that are inserted into the corpora cavernosa. The patient appears to have a permanent erection after the procedure; the patient is able to bend the penis into position at the time of intercourse.

The inflatable prosthesis has several mechanical parts. The inflatable prosthesis produces a more natural erection. The patient develops an erection only when the device is activated. Some newer advances in inflatable prosthesis technology have resulted in devices with fewer mechanical parts. These devices can be placed during shorter surgical procedures and have a low 5-year mechanical failure rate (6%–10%) as compared with the original inflatable prostheses (Fig. 92–7).[67]

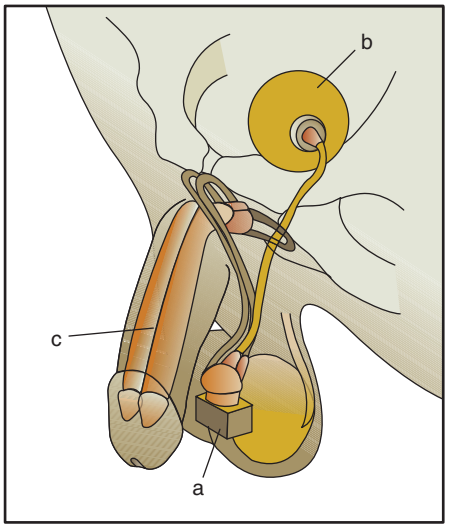

FIGURE 92-7. Example of surgically implanted penile prosthesis. (a, activation mechanism; b, reservoir with fluid for inflating prosthesis; c, inflatable rods in corpora.) *(From http://kidney.niddk.nih.gov/kudiseases/pubs/impotence.)*

Penile prostheses provide penile rigidity suitable for vaginal intercourse and are associated with a greater than 90% patient satisfaction rate, which is generally higher than that observed with any other drug treatment or VED.[68] The surgical success rate after insertion is 82% to 98%.[5]

Adverse effects of prosthesis insertion can occur early or late after the surgical procedure. The most common early complication is infection. Late complications include mechanical failure of the prosthesis, particularly when an inflatable prosthesis has been inserted. With improved technology, the mechanical failure rate has decreased to 5%.[5] Other late complications include erosion of the rods through the penis or late-onset infection. Although some salvage procedures have been devised, in many cases the prosthesis requires removal.

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcomes of specific treatments for erectile dysfunction include (1) improvement in the quantity and quality of penile erections suitable for intercourse and (2) avoidance of adverse drug reactions and drug interactions.

At baseline and after the patient has completed a clinical trial period of 1 to 3 weeks with a specific treatment for erectile dysfunction, the physician should conduct assessments to determine whether the quality and quantity of penile erections has improved. A patient's level of satisfaction is highly individualized, depending on his lifestyle and expectations. Therefore, a patient who has successful intercourse once per week might be completely satisfied, whereas another patient might judge this to be unsatisfactory. Patients with unrealistic expectations in this regard must be identified and counseled by clinicians to avoid adverse effects of excessive use of erectogenic agents.

Failure to improve the quality and quantity of penile erections suitable for intercourse after an appropriate clinical trial period with a specific treatment for erectile dysfunction occurs in a

significant percentage of patients. In this case, physicians generally take the following steps in order:

1. Ensure that the patient has been prescribed a maximum tolerated dose and has an adequate clinical trial of a specific treatment before discarding it as ineffective.
2. Switch to another drug (see Fig. 92–4).
3. Reserve surgical treatment for patients who do not respond to drug treatment.

CONCLUSIONS

Erectile dysfunction is a common disorder of aging men. Its incidence is higher in patients with underlying medical disorders that compromise the vascular, neurologic, hormonal, or psychogenic systems necessary for a normal penile erection. Medications are common causes of erectile dysfunction. By correcting the underlying etiology, erectile dysfunction can often be reversed without the use of specific treatments.

When treatments of erectile dysfunction are needed, the least invasive forms of treatment should be used first because they produce the lowest incidence of serious adverse effects. VEDs or phosphodiesterase inhibitors are considered first-line treatments. If these treatments fail, intracavernosal alprostadil injection therapy can be initiated. If this treatment fails, the patient can attempt a combination of intracavernosal alprostadil plus VED, combination intracavernosal therapy, or intraurethral alprostadil. If this treatment fails, the patient may require insertion of a penile prosthesis.

Some insurance companies do not reimburse for drug treatments for erectile dysfunction, so cost is an important issue for some patients.

Clinicians should provide clear and simple advice. Patient confidentiality and privacy, which are extremely important to men with erectile dysfunction, should be maintained at all times.

ABBREVIATIONS

cAMP: cyclic adenosine monophosphate

cGMP: cyclic guanosine monophosphate

VED: vacuum erection device

CHAPTER 93

Benign Prostatic Hyperplasia

MARY LEE

KEY CONCEPTS

1. Although symptomatic benign prostatic hyperplasia (BPH) is rare in men younger than 50 years of age, it is very common in men 60 years and older because of androgen-driven growth in the size of the prostate. Symptoms commonly result from both static and dynamic factors.
2. BPH symptoms may be exacerbated by medications, including antihistamines, phenothiazines, tricyclic antidepressants, and anticholinergic agents. In these cases, discontinuing the causative agent can relieve symptoms.
3. Specific treatments for BPH include watchful waiting, drug therapy, and surgery.
4. For patients with mild disease who are asymptomatic or have mildly bothersome symptoms and no complications of BPH disease, no specific treatment is indicated. These patients can be managed with watchful waiting. Watchful waiting includes behavior modification and return visits to the physician at 12-month intervals for assessment of worsening symptoms or signs of BPH.
5. If symptoms progress to a moderate or severe level, drug therapy or surgery is indicated. Drug therapy with an α_1-adrenergic antagonist is an interim measure that relieves voiding symptoms. In select patients with prostates of at least 40 g, 5α-reductase inhibitors delay symptom progression and reduce the incidence of BPH-related complications.
6. All α_1-adrenergic antagonists are equally effective in relieving BPH symptoms. Older second-generation immediate-release formulations of α_1-adrenergic antagonists (e.g., terazosin, doxazosin) can cause adverse cardiovascular effects, mainly first-dose syncope, orthostatic hypotension, and dizziness. For patients who can not tolerate hypotensive effects of the second-generation agents, the third-generation, pharmacologically uroselective agents (e.g., tamsulosin, silodosin) are good alternatives. An extended-release formulation of alfuzosin, a second-generation, functionally uroselective agent, has fewer cardiovascular adverse effects than immediate-release formulations of terazosin or doxazosin; however, whether extended-release doxazosin, alfuzosin, or silodosin have the same cardiovascular safety profile as tamsulosin is unclear.
7. 5α-Reductase inhibitors are useful primarily for patients with large prostates greater than 40 g who wish to avoid surgery and can not tolerate the side effects of α_1-adrenergic antagonists. 5α-Reductase inhibitors have a slow onset of action, taking up to 6 months to exert maximal clinical effects, which is a disadvantage of their use. In addition, decreased libido, erectile dysfunction, and ejaculation disorders are common adverse effects, which may be troublesome problems in sexually active patients.
8. Surgery is indicated for moderate to severe symptoms of BPH for patients who do not respond to or do not tolerate drug therapy or for patients with complications of BPH. It is the most effective mode of treatment in that it relieves symptoms in the greatest number of men with BPH. However, the two most widely used techniques, transurethral resection of the prostate and open prostatectomy, are associated with the highest rates of complications, including retrograde ejaculation and erectile dysfunction. Therefore, minimally invasive surgical procedures are often desired by patients. These relieve symptoms and are associated with a lower rate of adverse effects, but they have a higher reoperation rate than the gold standard procedures.
9. Although widely used in Europe for treatment of BPH, phytotherapy should be avoided. Studies of these herbal medicines are inconclusive, and the purity of available products is questionable.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm of American men. A nearly ubiquitous condition among elderly men, BPH is of major societal concern, given the large number of men affected, the progressive nature of the condition, and the healthcare costs associated with it.

This chapter discusses BPH and its available treatments: watchful waiting, α_1-adrenergic antagonists, 5α-reductase inhibitors, and surgery. The limitations of phytotherapy are described.

EPIDEMIOLOGY

1 According to the results of autopsy studies, approximately 80% of elderly men develop microscopic evidence of BPH. About half of the patients with microscopic changes develop an enlarged prostate gland, and as a result, they develop symptoms including difficulty emptying the contents from the urinary bladder. Approximately half of symptomatic patients eventually require treatment.

The peak incidence of clinical BPH occurs at 63 to 65 years of age. Symptomatic disease is uncommon in men younger than 50 years,

but some urinary voiding symptoms are present by the time men turn 60 years of age. The Boston Area Normative Aging Study estimated that the cumulative incidence of clinical BPH was 78% for patients at age 80 years.[1] Similarly, the Baltimore Longitudinal Study of Aging projected that approximately 60% of men at least 60 years old develop clinical BPH.[2]

NORMAL PROSTATE PHYSIOLOGY

Located anterior to the rectum, the prostate is a small heart-shaped, chestnut-sized gland located below the urinary bladder. It surrounds the proximal urethra like a doughnut.

Soft, symmetric, and mobile on palpation, a normal prostate gland in an adult man weighs 15 to 20 g. Physical examination of the prostate must be done by digital rectal examination (i.e., the prostate is manually palpated by inserting a finger into the rectum). Thus, the prostate is examined through the rectal mucosa.

The prostate has two major functions: (1) to secrete fluids that make up a portion (20%–40%) of the ejaculate volume and (2) to provide secretions with antibacterial effect possibly related to its high concentration of zinc.[2]

At birth, the prostate is the size of a pea and weighs approximately 1 g. The prostate remains that size until the boy reaches puberty. At that time, the prostate undergoes its first growth spurt, growing to its normal adult size of 15 to 20 g by the time the young man is 25 to 30 years of age. The prostate remains this size until the patient reaches age 40 years, when a second growth spurt begins and continues for the rest of his lifetime. During this period, the prostate can quadruple in size or grow even larger.

The prostate gland comprises three types of tissue: epithelial tissue, stromal tissue, and the capsule. Epithelial tissue, also known as *glandular tissue*, produces prostatic secretions. These secretions are delivered into the urethra during ejaculation and contribute to the total ejaculate volume. Androgens stimulate epithelial tissue growth. Stromal tissue, also known as *smooth muscle tissue*, is embedded with α_1-adrenergic receptors. Stimulation of these receptors by norepinephrine causes smooth muscle contraction, which results in an extrinsic compression of the urethra, reduction of the urethral lumen, and decreased urinary bladder emptying. The normal prostate is composed of a higher amount of stromal tissue than epithelial tissue, as reflected by a stromal-to-epithelial tissue ratio of 2:1. This ratio is exaggerated to 5:1 for patients with BPH, which explains why α_1-adrenergic antagonists are quickly effective in symptomatic management and why 5α-reductase inhibitors reduce an enlarged prostate gland by only 25%.[2,3] The capsule, or outer shell of the prostate, is composed of fibrous connective tissue and smooth muscle, which also is embedded with α_1-adrenergic receptors. When stimulated with norepinephrine, the capsule contracts around the urethra (Fig. 93–1).

Testosterone is the principal testicular androgen in males, whereas androstenedione is the principal adrenal androgen. These two hormones are responsible for penile and scrotal enlargement, increased muscle mass, and maintenance of the normal male libido. These androgens are converted by 5α-reductase in target cells to dihydrotestosterone (DHT), an active metabolite. Two types of 5α-reductase exist. Type I enzyme is localized to sebaceous glands in the frontal scalp, liver, and skin. DHT produced at these target tissues causes acne and increased body and facial hair. Type II enzyme is localized to the prostate, genital tissue, and hair follicles of the scalp. In the prostate, DHT induces growth and enlargement of the gland.[3]

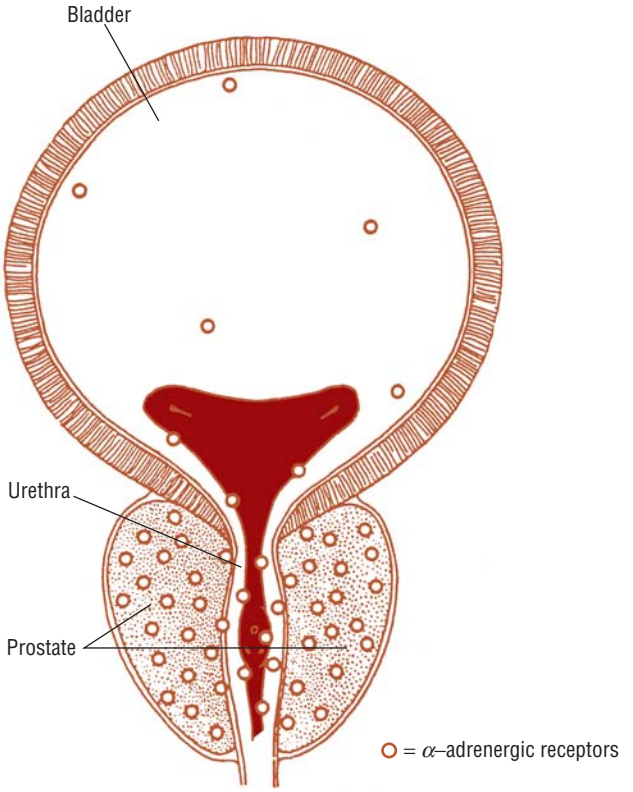

FIGURE 93-1. Representation of the anatomy of and α-adrenergic receptor distribution in the prostate, urethra, and bladder. *(Western Journal of Medicine 1994;161:501. Reproduced with permission from the BMJ Publishing Group.)*

In prostate cells, DHT has greater affinity for intraprostatic androgen receptors than testosterone, and DHT forms a more stable complex with the androgen receptor. Thus, DHT is considered a more potent androgen than testosterone in the prostate. Of note, despite the decrease in testicular androgen production in the aging male, intracellular DHT levels in the prostate remain normal, probably due to increased activity of intraprostatic 5α-reductase.[3]

Estrogen, a product of peripheral metabolism of androgens, is believed to stimulate the growth of the stromal portion of the prostate gland. Estrogens are produced when testosterone and androstenedione are converted by aromatase enzymes in peripheral adipose tissues. In addition, estrogens may induce the androgen receptor.[2] As men age, the ratio of serum levels of testosterone to estrogen decreases as a result of a decline in testosterone production by the testes and increased adipose tissue conversion of androgen to estrogen.

PATHOPHYSIOLOGY

Although the precise pathophysiologic mechanisms causing BPH remain unclear, the role of intraprostatic DHT and type II 5α-reductase in the development of BPH is evidenced by several observations:

- BPH does not develop in men who are castrated before puberty.
- Patients with type II 5α-reductase enzyme deficiency do not develop BPH.
- Castration causes an enlarged prostate to shrink.

- Administration of testosterone to orchiectomized dogs of advanced age produces BPH.

The pathogenesis of BPH is often described as resulting from both static and dynamic factors. Static factors relate to anatomic enlargement of the prostate gland, which produces a physical block at the bladder neck and thereby obstructs urinary outflow. Enlargement of the gland depends on androgen stimulation of epithelial tissue and estrogen stimulation of stromal tissue in the prostate. Dynamic factors relate to excessive α-adrenergic tone of the stromal component of the prostate gland, bladder neck, and posterior urethra, which results in contraction of the prostate gland around the urethra and narrowing of the urethral lumen.

Symptoms of BPH disease may result from static and/or dynamic factors, and this must be recognized when drug therapy is considered. For instance, some patients may present with obstructive voiding symptoms but have prostates of normal size. In these patients, dynamic factors likely are responsible for the symptoms. However, for patients with enlarged prostate glands, static and dynamic factors likely are working in concert to produce the observed symptoms. Moreover, the likelihood of developing moderate to severe voiding symptoms is directly related to the increasing size of the prostate gland.[4]

Static factors may be accentuated if the patient becomes stressed or is in pain. In these situations, increased α-adrenergic tone may precipitate excessive contraction of prostatic stromal tissue. When the stressful event resolves, voiding symptoms often improve.[2]

MEDICATION-RELATED SYMPTOMS

2 Medications in several pharmacologic categories should be avoided for patients with BPH because they may exacerbate symptoms.[5] Testosterone replacement regimens, used to treat primary or secondary hypogonadism, deliver additional substrate that can be metabolized to DHT by the prostate. Although no cases of BPH have been reported because of exogenous testosterone administration, cautious use is advised for patients with prostatic enlargement. α-Adrenergic agonists, used as oral or intranasal decongestants (e.g., pseudoephedrine, ephedrine, or phenylephrine), can stimulate α-adrenergic receptors in the prostate, resulting in muscle contraction. By decreasing the caliber of the urethral lumen, bladder emptying may be compromised. Drugs with significant anticholinergic adverse effects (e.g., antihistamines, phenothiazines, tricyclic antidepressants, or anticholinergic drugs used as antispasmodics or to treat Parkinson disease) may decrease contractility of the urinary bladder detrusor muscle. For patients with BPH who have a narrowed urethral lumen, loss of effective detrusor contraction could result in acute urinary retention, particularly for patients with significantly enlarged prostate glands. Diuretics, particularly in large doses, can produce polyuria, which may present as urinary frequency, similar to that experienced by patients with BPH.

CLINICAL PRESENTATION

Patients with BPH can present with a variety of symptoms and signs of disease. All symptoms of BPH can be divided into two categories: obstructive and irritative.

Obstructive symptoms, also known as *prostatism* or *bladder outlet obstruction*, result when dynamic and/or static factors reduce bladder emptying. The force of the urinary stream becomes diminished, urinary flow rate decreases, and bladder emptying is incomplete and slow. Patients report urinary hesitancy and straining and a weak urine stream. Urine dribbles out of the penis, and the urinary bladder always feels full, even after patients have voided. Some patients state that they need to press on their bladder to force out the urine. In severe cases, patients may go into urinary retention when bladder emptying is not possible. In these cases, suprapubic pain can result from bladder overdistension.

Approximately 50% to 80% of patients have irritative voiding symptoms, which typically occur late in the disease course. Irritative voiding symptoms result from long-standing obstruction at the bladder neck. To compensate, the bladder muscle undergoes hypertrophy so that it can generate a greater contractile force to empty urine past the anatomic obstruction at the bladder neck. Although initially helpful, decompensation eventually occurs, and the hypertrophied bladder muscle is no longer able to generate adequate contractile force as it becomes hypersensitive and ineffective in storing urine. As a result, small amounts of urine irritate the bladder and initiate a bladder emptying response. Patients complain of urinary frequency and urgency. Bedwetting or clothes wetting occurs. Patients report waking up every 1 to 2 hours at night to void (nocturia), which significantly reduces quality of life.

Symptoms of BPH vary over time. Symptoms may improve, remain stable, or worsen spontaneously. Thus, BPH is not necessarily a progressive disease; in fact, some patients experience symptom regression. Between one and two thirds of men with mild disease stabilize or improve without treatment over 2.5 to 5 years.[2] However, other patients experience a slow progression of disease.

Collectively, obstructive and irritative voiding symptoms and their impact on a patient's quality of life are referred to as *lower urinary tract symptoms* (LUTS). However, LUTS is not pathognomonic for BPH and may be caused by other diseases, such as neurogenic bladder and urinary tract infection.[2]

Another presentation of BPH is silent prostatism. Patients have obstructive or irritative voiding symptoms but adapt to them and do not voluntarily complain about them. Such patients do not present for medical treatment until complications of BPH disease arise or a spouse brings in a symptomatic patient for medical care.

CLINICAL PRESENTATION OF BENIGN PROSTATIC HYPERPLASIA

General

- Patient is in no acute distress unless he has moderate to severe symptoms or complications of BPH

Symptoms

- Urinary frequency, urgency, intermittency, nocturia, decreased force of stream, hesitancy, and straining

Signs

- Digital rectal examination reveals an enlarged prostate (>20 g) with no nodules or indurations; prostate is soft, symmetric, and mobile

Laboratory Tests

- Increased blood urea nitrogen (BUN) and serum creatinine with long-standing, untreated bladder outlet obstruction, elevated prostate-specific antigen (PSA) level

Other Diagnostic Tests

- Increased American Urological Association (AUA) Symptom Score, decreased urinary flow rate (<10 mL/s), and increased postvoid residual (PVR) urine volume

BPH can be a progressive disease, although the rate of progression is variable among patients.[2] When BPH progresses, it can produce complications that include the following:

- Acute, painful urinary retention, which can lead to acute renal failure
- Persistent gross hematuria when tissue growth exceeds its blood supply
- Overflow urinary incontinence or unstable bladder
- Recurrent urinary tract infection that results from urinary stasis
- Bladder diverticula
- Bladder stones
- Chronic renal failure from long-standing bladder outlet obstruction

Approximately 17% to 20% of patients with symptomatic BPH require treatment because of disease complications.[6] Older men with large prostates greater than 40 g are three times more likely to have severe symptoms or suffer from acute urinary retention and to require prostatectomy than patients with smaller prostates.[7,8] Thus, a serum PSA level of 1.4 ng/mL (1.4 mcg/L) has been used as a surrogate marker for an enlarged prostate gland to identify patients at risk for developing complications of BPH disease[6] and has been used to guide selection of the most appropriate treatment modality in some patients.[9,10]

DIAGNOSTIC EVALUATION

Because the obstructive and irritative voiding symptoms associated with BPH are not unique to the disease and can be presenting symptoms of other genitourinary tract disorders, including prostate or bladder cancer, neurogenic bladder, prostatic calculi, or urinary tract infection, the patient presenting with signs and symptoms of BPH must be thoroughly evaluated.

A careful medical history should be taken to ensure that a complete listing of symptoms is collected as well as to identify concomitant disorders that may be contributing to voiding symptoms. The medical history should be followed by a thorough medication history, including all prescription and nonprescription medications and dietary supplements that the patient is taking. Any drugs that could be causing or exacerbating the patient's symptoms should be identified. If possible, the suspected drugs should be discontinued or the dosing regimen modified to ameliorate the voiding symptoms.

The patient should undergo a physical examination, including a digital rectal examination, although the size of the prostate gland may not correspond to symptoms. BPH usually presents as an enlarged, soft, smooth, symmetric gland, greater than 20 g in size. Some patients have only a slightly enlarged gland and yet have bothersome or even serious voiding difficulties. Other patients have an intravesical enlargement of the prostate gland (i.e., the gland grows into the urinary bladder and produces a ball-valve blockage of the bladder neck). This type of prostate enlargement is not palpable on manual examination.

The patient's perception of the severity of BPH symptoms guides selection of a particular treatment modality in a patient. To evaluate the patient's perceptions objectively, validated instruments, such as the AUA Symptom Score, are commonly used. Using the AUA index, the patient rates the "bothersomeness" of seven obstructive and irritative voiding symptoms.[2,11] Each item is rated for severity on a scale from 0 to 5, such that 35 is the maximum score and is consistent with the most severe symptoms. In addition, the patient can complete a voiding diary in which he records the number of voids, the volume of each void, and voiding symptoms for several days. This information is used to evaluate symptom severity and to tailor recommendations for lifestyle modifications that may ameliorate symptoms.

The only clinical laboratory test that must be performed is a urinalysis. Because many of the voiding symptoms of BPH could be caused by other urologic disorders, a urinalysis can help screen for bladder cancer, stones, and infection. To screen for prostate cancer, another common cause of glandular enlargement, a PSA test should be performed for patients aged 40 years or more, with at least a 10-year life expectancy in whom the cost of the test will be outweighed by the potential benefit of diagnosing the disorder.[11]

Additional objective measures of bladder emptying should be performed if surgical treatment is being considered. Measures include peak and average urinary flow rate (normal is at least 10 mL/s). These measures are determined using a uroflowmeter, which checks the rate of urine flow out of the bladder. This is a quick noninvasive outpatient procedure in which the patient is instructed to drink water until his bladder feels full and then the patient's urinary flow is clocked during voiding. A low urinary flow rate (<10 to 12 mL/s) implies failure of bladder emptying or a functional disorder of the detrusor muscle. Thus, the degree of bladder outlet obstruction correlates poorly with peak urinary flow rate.[11]

Another objective measure is PVR urine volume (normal is 0 mL), which is assessed using a transabdominal ultrasound. A high PVR urine volume (>25 to 30 mL) implies failure of bladder emptying and a predisposition for urinary tract infections. Because of a weak correlation among voiding symptoms, prostate size, and urinary flow rate, most physicians use a combination of measures, including the patient's assessment of symptoms along with objective evaluation of urinary outflow and presence of complications of BPH to determine the need for treatment.

Many other tests can be performed if additional information is needed to assess the severity of BPH disease and its complications, to assist in the preoperative assessment of the patient, or to distinguish prostate enlargement due to BPH from that caused by prostate cancer. Tests include a serum BUN and creatinine, voiding cystometrogram, transrectal ultrasound of the prostate, intravenous pyelogram, renal ultrasound, and prostate biopsy.

TREATMENT

Benign Prostatic Hyperplasia

As a disease of symptoms, BPH is treated by relieving bothersome symptoms. Patients usually are stratified into three groups based on disease severity for the purposes of deciding a treatment approach (Table 93–1). However, literature about the natural history of BPH

TABLE 93-1 Categories of BPH Disease Severity Based on Symptoms and Signs

Disease Severity	AUA Symptom Score	Typical Symptoms and Signs
Mild	≤7	Asymptomatic Peak urinary flow rate <10 mL/s Postvoid residual urine volume >25–50 mL
Moderate	8–19	All of the above signs plus obstructive voiding symptoms and irritative voiding symptoms (signs of detrusor instability)
Severe	≥20	All of the above plus one or more complications of BPH

AUA, American Urological Association; BPH, benign prostatic hyperplasia; BUN, blood urea nitrogen.

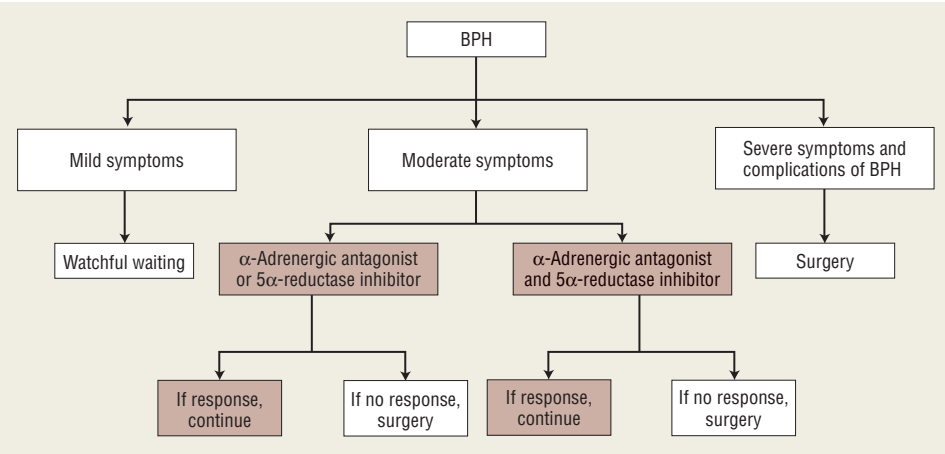

FIGURE 93-2. Management algorithm for benign prostatic hyperplasia (BPH).

and the significant risk of disease complications suggests that physicians also should consider preventing serious complications of BPH and decreasing the need for surgery as goals of treatment for select patients. This is a controversial topic complicated by many issues, including the variable costs of treatment options, the inability to clearly distinguish patients who experience spontaneous regression or disease stabilization from those in whom symptoms progress, and the potential benefit that may occur in a comparatively small number of treated patients.

The AUA Guidelines on Management of Benign Prostatic Hyperplasia is the principal tool used in the United States,[11] and the AUA recommendations are similar to the European[12] and Canadian Practice Guidelines (Fig. 93–2).[13]

3 All patients should be encouraged to initiate and maintain a heart healthy lifestyle, including a low fat diet, high intake of plenty of fresh fruits and vegetables, regular physical exercise, and no smoking.[14] Specific treatment options include watchful waiting, pharmacologic therapy, and surgical intervention. Although phytotherapy is used by some patients alone or along with conventional medications for BPH, head-to-head comparisons with U.S. Food and Drug Administration (FDA)-approved treatments are lacking; consequently, such herbals can not be recommended at this time.

4 Patients with mild disease are asymptomatic or have mildly bothersome symptoms and have no complications of BPH disease. For these patients, no specific treatment is indicated. These patients can be managed with watchful waiting, which entails having the patient return for reassessment at yearly intervals. At each return visit, the patient should complete a standardized, validated survey tool to assess severity of symptoms. Watchful waiting should be accompanied by patient education about the disease and behavior modification to avoid practices that exacerbate voiding symptoms. Behavior modification includes restricting fluids close to bedtime, minimizing caffeine and alcohol intake, frequent emptying of the bladder during waking hours (to avoid overflow incontinence and urgency), and avoiding drugs that could exacerbate voiding symptoms.[15] At each visit, physicians should assess the patient's risk of developing acute urinary retention by evaluating the patient's prostate size or using PSA as a surrogate marker of prostate enlargement.[11]

5 If symptoms progress to the moderate or severe level, or the patient perceives his symptoms to be bothersome, the patient should be offered specific treatment. In these patients, watchful waiting delays—but does not decrease—the need for prostatectomy. In symptomatic patients, watchful waiting can lead to intractable urinary retention, increased PVR urine volumes, and significant voiding symptoms.[16] Recommended treatment options include drug therapy with an α_1-adrenergic antagonist or 5α-reductase inhibitor, a combination of an α_1-adrenergic antagonist and a 5α-reductase inhibitor, or surgery.

Patients with serious complications of BPH should be offered surgical correction (transurethral or open prostatectomy, or a minimally invasive surgical procedure). Drug therapy is considered an interim measure for such patients because it only delays worsening of complications and the need for surgical intervention.[11,16]

PHARMACOLOGIC THERAPY

Drug therapy for BPH can be categorized into three types: agents that relax prostatic smooth muscle (reducing the dynamic factor), agents that interfere with testosterone's stimulatory effect on prostate gland enlargement (reducing the static factor), and combination therapy of an α_1-adrenergic antagonist and a 5α-reductase inhibitor (Table 93–2). Of the agents that relax prostatic smooth muscle, second- and third-generation α_1-adrenergic antagonists have been most widely used. These agents relax the intrinsic urethral sphincter and prostatic smooth muscle, thereby enhancing urinary outflow from the bladder. α_1-Adrenergic antagonists do not reduce prostate size. Of the agents that interfere with testosterone's stimulatory effect on prostate gland size, the only agents approved by the FDA are 5α-reductase inhibitors (e.g., finasteride, dutasteride). Other agents that interfere with androgen stimulation of the prostate have not been popular in the United States because of the many adverse effects associated with their use. The luteinizing hormone-releasing

TABLE 93-2 Medical Treatment Options for Benign Prostatic Hyperplasia

Category	Mechanism	Drug (Brand Name)
Reduces dynamic factor	Blocks α_1-adrenergic receptors in prostatic stromal tissue	Prazosin (Minipress) Alfuzosin (Uroxatral) Terazosin (Hytrin) Doxazosin (Cardura)
	Blocks α_{1A}-receptors in the prostate	Tamsulosin (Flomax) Silodosin (Rapaflo)
Reduce static factor	Blocks 5α-reductase enzyme	Finasteride (Proscar) Dutasteride (Avodart)
	Blocks dihydrotestosterone at its intracellular receptor	Bicalutamide (Casodex)[a] Flutamide (Eulexin)[a]
	Blocks pituitary release of luteinizing hormone	Leuprolide (Lupron)[a] Goserelin (Zoladex)[a]
	Blocks pituitary release of luteinizing hormone and blocks androgen receptor	Megestrol acetate (Megace)[a]

[a]Not FDA approved for treatment of benign prostatic hyperplasia.

hormone superagonists leuprolide and goserelin decrease libido and can cause erectile dysfunction, gynecomastia, and hot flashes. Antiandrogens (e.g., bicalutamide, flutamide) produce nausea, diarrhea, and hepatotoxicity.

Selection of a medical treatment for a patient should be determined on a case-by-case basis after patient and provider discussion of risks, benefits, and costs of various treatments. With drug therapy for BPH, patients must understand that the benefits continue only as long as the medication is taken.

If possible, drug therapy should be initiated with a single agent, usually an α_1-adrenergic antagonist, which is faster acting and more effective than a 5α-reductase inhibitor. In addition, α_1-adrenergic antagonists are effective in reducing LUTS independent of prostate size, have no effect on PSA, and are associated with less sexual dysfunction than are 5α-reductase inhibitors. A 5α-reductase inhibitor is a good first-choice agent for patients with a significantly enlarged prostate (>40 g) who can not tolerate the cardiovascular adverse effects of α_1-adrenergic antagonists. For patients at risk for developing complications of BPH, specifically patients with an enlarged prostate gland greater than 40 g[6,17] and an elevated PSA ≥1.4 ng/mL (1.4 mcg/L), combination drug therapy with an α_1-adrenergic antagonist and a 5α-reductase inhibitor is more beneficial than single drug therapy. The pharmacologic rationale for such a combination is that using two drugs with different mechanisms of action can be more effective than either drug alone. The clinical benefit of combination therapy is that it quickly relieves symptoms, delays disease progression and reduces the need for surgical intervention.

α-Adrenergic Antagonists

Three generations of α-adrenergic antagonists have been used to treat BPH. They all relax smooth muscle in the prostate and bladder neck. Because of their antagonism of presynaptic α2-adrenergic receptors that results in tachycardia and arrhythmias, first-generation agents such as phenoxybenzamine have been replaced by the second-generation postsynaptic α_1-adrenergic antagonists and third-generation uroselective postsynaptic α_1-adrenergic antagonists.

6 The second- and third-generation α_1-adrenergic antagonists are considered equally effective for treatment of BPH.[11,18,19] These agents generally improve the AUA Symptom Score by 30% to 40% within 2 to 6 weeks, depending on the need for up dose titration, increase urinary flow rate by 2 to 3 mL/s in 60% to 70% of treated patients, and reduce PVR urine volume. They have no effect on decreasing prostate volume. Finally, α_1-adrenergic antagonists do not reduce PSA levels, preserving the utility of this prostate cancer marker in this high-risk population.[11]

Second-generation agents include prazosin, terazosin, doxazosin, and alfuzosin. At the usual doses used to treat BPH, prazosin, terazosin, and doxazosin antagonize peripheral vascular α_1-adrenergic receptors in addition to those in the prostate. As a result, first-dose syncope, orthostatic hypotension, and dizziness are characteristic adverse effects. To improve tolerance to these adverse effects, therapy should start with a low dose of 1 mg daily and then should be slowly titrated up to a full therapeutic dose over several weeks.[20,21] Additive blood-pressure-lowering effects commonly occur when these agents are used with antihypertensive agents, which limit use of these agents for some patients. These agents differ in terms of duration of action and dosage formulation. Whereas prazosin requires dosing two to three times per day, terazosin, doxazosin, and alfuzosin offer more convenient once daily dosing. Because prazosin requires twice to thrice daily dosing and has significant cardiovascular adverse effects, it is not recommended in the current AUA guidelines for treatment of BPH.[11] Extended-release dosage formulations are available for doxazosin and alfuzosin. These offer the convenience of once daily dosing, treatment initiation with a full therapeutic dose, and decreased dose-related hypotension as the formulation produces lower peak serum concentrations than immediate-release products.[6,22–24] An α_1-adrenergic antagonist is not preferred as single-drug therapy for treatment of both BPH and hypertension in a patient. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) of 24,000 patients with hypertension, doxazosin produced more congestive heart failure than amlodipine, lisinopril, or chlorthalidone.[25] Thus, both the AUA and the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure[26] recommend that patients with BPH and hypertension be treated with separate and appropriate drug treatment for each medical condition.[27]

Alfuzosin is considered functionally and clinically uroselective in that usual doses used to treat BPH are less likely than other second-generation agents to cause cardiovascular adverse effects in animal or human models.[23] This clinical observation has been seen more often with the once daily, extended-release formulation of alfuzosin, which is the only commercially available formulation in the United States, as compared with the immediate-release formulation that is dosed three times per day, which is available in Europe.[28] Its clinical uroselectivity has been postulated to be due to higher concentrations of alfuzosin achieved in the prostate versus serum after usual doses,[29] decreased blood–brain barrier penetration of alfuzosin,[23] absence of high peak serum levels with the extended-release formulation,[30] and fixed dosing schedule of the extended-release formulation. Extended-release alfuzosin dosing is FDA approved for 10 mg daily, with no dose titration increase.[28] This formulation is particularly convenient for physician prescribers and patients who are starting to take the medication.

Tamsulosin and silodosin are the only third-generation α_1-adrenergic antagonists available in the United States. They are an advance over second-generation agents in that they are selective for prostatic α_{1A}-adrenergic receptors, which comprise approximately 70% of the adrenergic receptors in the prostate gland.[31,32] Blockade of these receptors results in smooth muscle relaxation of the prostate and bladder neck without causing peripheral vascular smooth muscle relaxation. Tamsulosin and silodosin have low affinity for vascular α_{1B}-adrenergic receptors, which explains why hypotension is not a common adverse effect.

Tamsulosin's selectivity for α_{1A}-adrenergic receptors has multiple implications. Dose titration is minimal; therefore, patients can begin therapy with the lowest effective maintenance dose of 0.4 mg/day taken orally. Patients can be instructed to take the dose anytime during the day, unlike immediate-release formulations of terazosin and doxazosin, which should be taken at bedtime so that patients can sleep through the time when peak cardiovascular adverse effects are most likely to occur. However, for best oral absorption, tamsulosin should be taken on an empty stomach because food decreases the drug's bioavailability and reduces the peak serum concentration of the drug after dosing. The onset of peak action is quick, in the range of 1 week, and only a minority of patients will require uptitration to a higher daily dose. No decreases in blood pressure or increases in heart rate have been reported in normotensive patients, the elderly, subgroups of patients with well-controlled hypertension, or those with uncontrolled hypertension.[33] Thus, tamsulosin allows initiation of treatment with a therapeutic dose that is not limited by cardiovascular adverse effects, unlike immediate-release formulations of terazosin and doxazosin.[34] Finally, the addition of tamsulosin to select antihypertensive regimens of patients does not result in potentiation of the hypotensive effect of furosemide, enalapril, nifedipine, and atenolol.[35,36] Therefore, tamsulosin is a good choice, particularly for patients who can not tolerate hypotension; have severe coronary artery disease, volume depletion, cardiac

TABLE 93-3 Dosing Schedule of α_1-Adrenergic Antagonists for Patients with Benign Prostatic Hyperplasia

Drug	Half-life (h)	Usual Daily Dosage	Time to Peak Effect on BPH Symptoms[a]
Prazosin (Minipress)	2–3	2–10 mg in two to three divided doses	2–6 weeks
Terazosin (Hytrin)	11–14	1–10 mg as a single dose; maximum 20 mg	2–6 weeks
Doxazosin (Cardura)	15–19	1–4 mg as a single dose; maximum 8 mg	2–6 weeks
Doxazosin GTS (Cardura XL)	15–19	4 or 8 mg as a single dose, maximum 8 mg	Several days
Alfuzosin (Uroxatral)	10	10 mg as a single dose	Several days
Tamsulosin (Flomax)	14–15	0.4 or 0.8 mg as a single dose	Several days
Silodosin (Rapaflo)	13	8 mg as a single dose	Several days

[a]Time to peak effect on benign prostatic hyperplasia (BPH) symptoms is dependent on the titration period to achieve full therapeutic daily doses.

arrhythmias, severe orthostasis, or liver failure; are taking multiple antihypertensives; or when the titration would be too complicated for the patient or produce an unacceptable delay in onset for a particular patient.

As compared with tamsulosin, silodosin requires dosage modification for patients with renal and hepatic impairment, has the potential for more drug interactions with inhibitors of CYP 3A4 (e.g., clarithromycin) and P-glycoprotein (e.g., cyclosporine), and has much less clinical experience with its use for patients with cardiovascular disease. For these reasons, tamsulosin is the preferred third-generation α_1-adrenergic antagonist in clinical practice.[32]

The usual doses of α_1-adrenergic antagonists are summarized in Table 93–3.

When using immediate-release formulations of the second-generation α_1-adrenergic antagonists terazosin and doxazosin, slow titration up to a therapeutic maintenance dose is necessary to minimize orthostatic hypotension and first-dose syncope. Conservatively, dosages should be increased in an orderly stepwise process, at 2- to 7-day intervals, depending on the patient's response to the medication. A faster titration schedule can be used as long as the patient does not develop orthostatic hypotension or dizziness. Two sample titration schedules for terazosin are as follows:

- **Schedule 1: Slow titration**
  Days 4 to 14: 2 mg at bedtime
  Weeks 2 to 6: 5 mg at bedtime
  Weeks 7 and on: 10 mg at bedtime
- **Schedule 2: Quicker titration**
  Days 1 to 3: 1 mg at bedtime
  Days 4 to 14: 2 mg at bedtime
  Weeks 2 to 3: 5 mg at bedtime
  Weeks 4 and on: 10 mg at bedtime

Patients should continue taking the drug as long as they continue to respond to it. Durable responses for 6 and 10 years have been reported for tamsulosin[37] and doxazosin,[38] respectively. If BPH symptoms worsen despite maximum tolerable drug doses, surgery should be considered.

With the exception of silodosin, no dosage adjustments are recommended for α_1-adrenergic antagonists for patients with renal failure. Because these drugs are hepatically catabolized, the lowest effective dose should be used for patients with hepatic dysfunction, and patients should be monitored carefully for adverse effects. With the exception of silodosin, no specific dosing guidelines for this patient population are available. For silodosin, a reduced daily dose of 4 mg is recommended for patients with moderate renal impairment or those with hepatic dysfunction.

Approximately 10% to 12% of patients discontinue taking second-generation α_1-adrenergic antagonists because of adverse effects, especially those that affect the cardiovascular system (e.g., syncope, dizziness, hypotension).[39] Patients who tolerate hypotension poorly should avoid second-generation α_1-adrenergic antagonists. This includes patients with poorly controlled angina, serious cardiac arrhythmias, patients with reduced circulating volume, and patients taking multiple antihypertensives.[39] These patients are candidates for a third-generation α_1-adrenergic antagonist or finasteride, if drug therapy is deemed necessary. Whether extended-release alfuzosin or silodosin is a good choice remains to be elucidated in controlled comparison trials with tamsulosin.[40,41]

Tiredness and asthenia, ejaculatory dysfunction, flu-like symptoms, and nasal congestion are the most common dose-related adverse effects of tamsulosin and silodosin.[42] These adverse effects are extensions of their α-adrenergic antagonist activity and are unavoidable, but with proper education patients likely will not discontinue treatment.

Floppy iris syndrome has been associated with doxazosin, silodosin, and tamsulosin use, although the number of reported cases is highest with tamsulosin.[42,43] The mechanism for this adverse reaction is related to blockade of α_{1A}-adrenergic receptors in iris dilator muscles. As a result, during cataract surgery, papillary constriction occurs and the iris billows out (floppy iris), both of which complicate the procedure or can increase the likelihood of postoperative complications.[42–45] Patients who are taking α_1-adrenergic antagonists and who plan to undergo cataract surgery should inform their ophthalmologist that they are taking this medication so that appropriate measures can be taken during eye surgery, e.g., use of iris retractors, papillary expansion rings, or potent mydriatic agents.[43] Patients with severe sulfa allergy should avoid tamsulosin.

Caution is needed when CYP 3A4 inhibitors, e.g., cimetidine, diltiazem are used with α_1-adrenergic antagonists because a drug–drug interaction could lead to decreased metabolism of the latter agents. In contrast, concurrent use of potent CYP 3A4 stimulators, e.g., carbamazepine and phenytoin, may increase hepatic catabolism of α_1-adrenergic antagonists.

Phosphodiesterase inhibitors (e.g., sildenafil, vardenafil, tadalafil) may produce systemic hypotension if used in large doses along with α_1-adrenergic antagonists. The mechanisms for this interaction are related to the intrinsic vasodilatory effects of phosphodiesterase inhibitors and the higher susceptibility of elderly patients to venous pooling because of autonomic incompetence.[27,46] Therefore, package labeling for these drugs includes a caution to carefully monitor patients who are taking phosphodiesterase inhibitors with α_1-adrenergic antagonists.

CURRENT CONTROVERSY

Among the α_1-adrenergic antagonists, tamsulosin and extended-release alfuzosin have been associated with the highest and lowest incidences of ejaculatory dysfunction, respectively. Although some clinicians claim that this difference should be considered when selecting one agent over another, this adverse effect is of variable clinical significance. Some patients complain of decreased sexual satisfaction because of ejaculatory dysfunction, whereas other patients do not.

5α-Reductase Inhibitors

7 Finasteride competitively inhibits type II 5α-reductase, suppresses intraprostatic DHT by 80% to 90%, and decreases serum DHT levels by 70%.[9] Dutasteride is a nonselective inhibitor of type I and II 5α-reductase. It more quickly and completely suppresses intraprostatic DHT production and decreases serum DHT levels by 90%.[47] However, direct comparison clinical trials show no advantages of these pharmacodynamic actions of dutasteride when compared with finasteride.[48] These agents are indicated for management of moderate to severe BPH disease for patients with enlarged prostate glands of at least 40 g.[48] For such patients, 5α-reductase inhibitors may slow disease progression and decrease the risk of disease complications, thereby decreasing the ultimate need for surgical intervention. When taken continuously for 6 years, finasteride has been shown to decrease the risk of acute urinary retention and prostatectomy.[49] For patients with severe disease, these agents generally can be used with a 6-month short course of an α_1-adrenergic antagonist, which will provide fast symptom relief until the 5α-reductase inhibitor starts to work. 5α-Reductase inhibitors may be preferred for patients with BPH and an enlarged prostate gland who have uncontrolled arrhythmias, have poorly controlled angina, are taking multiple antihypertensive agents, or are unable to tolerate hypotensive adverse effects of α_1-adrenergic antagonists.

5α-Reductase inhibitors reduce prostate size by 25%, increase peak urinary flow rate by 1.6 to 2.0 mL/s, improve voiding symptoms in approximately 30% of treated patients, and produce few serious adverse effects. Compared with α_1-adrenergic antagonists, 5α-reductase inhibitors have several disadvantages. 5α-Reductase inhibitors have a delayed peak onset of clinical effect, which is undesirable for patients with bothersome symptoms, and an adequate clinical trial is 6 to 12 months. In addition, the percentage of patients who experience objective improvement is less with 5α-reductase inhibitors than with α_1-adrenergic antagonists. 5α-Reductase inhibitors cause more sexual dysfunction than α_1-adrenergic receptor antagonists; therefore, physicians consider 5α-reductase inhibitors to be second-line agents for treatment of BPH in sexually active males (Table 93–4).[11]

Patients with BPH who have large prostate glands, PSA level less than 3 ng/mL (3 mcg/L) and are concerned about developing prostate cancer can be prescribed finasteride 5 mg daily for up to 7 years, which has been shown to reduce the 7-year prevalence of prostate cancer by 25% in the Prostate Cancer Prevention Trial.[50,51] However, in this study, finasteride was associated with a small increased risk of developing a higher-grade prostate cancer, which has a potential for invasiveness. Although originally thought to be an adverse effect of finasteride use, it is now thought that the higher incidence of prostate cancer is due to biopsy sampling bias. That is, since finasteride reduces the size of the prostate gland, this results in increased sensitivity of sampling biopsies to detect prostate cancer. The ongoing Reduction by Dutasteride in Prostate Cancer Events (REDUCE) trial should provide additional information on the value of 5α-reductase inhibitors in preventing prostate cancer.[52]

Finasteride is well absorbed from the gastrointestinal tract (95%), and its absorption is unaffected by food. Peak serum concentrations are reached 1 to 2 hours after the dose. Finasteride is highly protein bound. The liver extensively metabolizes finasteride to inactive metabolites, which are largely excreted in stool. The plasma half-life is 4.7 to 7.1 hours, but its biologic half-life probably is longer, as decreased serum DHT levels persist for up to 2 weeks after finasteride dosing is stopped.

For BPH, finasteride is given in doses of 5 mg by mouth daily. The dose can be taken with meals or on an empty stomach. No dosage adjustment is needed for patients with renal dysfunction. Although no dosage reduction is recommended for patients with hepatic insufficiency, patients should be monitored carefully. Maximal reductions in prostate volume or symptom improvement may not be evident for 12 months, but noticeable changes from baseline should occur after 6 months of continuous treatment. No clinically relevant drug interactions have been reported with 5α-reductase inhibitors.

Patients must continue to take 5α-reductase inhibitors as long as they respond. Durable responses to finasteride and dutasteride have been reported with continued treatment for 6 years[49] and 4 years,[48] respectively. Upon discontinuation of the drug, prostate size and voiding symptoms generally return to baseline.

5α-Reductase inhibitors can produce sexual dysfunction, and this has led to discontinuation of therapy in up to 12% of treated patients in one pooled analysis.[48] Ejaculation disorders (dry sex or delayed ejaculation) have been reported in 3% to 8% of treated patients.[53] These disorders, which are possible results of decreased prostatic secretion, are reversible with drug discontinuation.

Erectile dysfunction has been reported for 3% to 16% of patients.[48] It may be secondary to ejaculation disorders or may be due to drug-induced inhibition of nitric oxide synthase (which is needed to produce nitric oxide, a vasodilatory substance) in cavernosal tissue.[54] The role of 5α-reductase inhibitors in causing erectile dysfunction is not clear, as elderly men with BPH commonly develop erectile dysfunction as they age or have concurrent medical illnesses or concomitant drug therapies that may predispose to the development of sexual dysfunction.[53] Decreased libido has been reported in 2% to 10% of treated patients.[48]

Other minor adverse effects include nausea, abdominal pain, asthenia, dizziness, flatulence, headache, rash, muscle weakness, and gynecomastia.

5α-Reductase inhibitors are in FDA pregnancy category X, which means that they are contraindicated in pregnant females. Exposure of the male fetus to finasteride may produce pseudohermaphroditic offspring with ambiguous genitalia, similar to those of patients with a rare genetic deficiency of type II 5α-reductase. Because of this teratogenic effect, women who are pregnant or seeking to become pregnant should not handle 5α-reductase inhibitor tablets and should not have contact with semen from men being treated with 5α-reductase inhibitors. Women pharmacists of childbearing age should handle this product with rubber gloves if there is any chance that they are pregnant.

Usual doses of 5α-reductase inhibitors produce a median reduction of serum PSA levels by 50%. For this reason, PSA levels must

TABLE 93-4 Comparison of α_1-Adrenergic Antagonists and 5α-Reductase Inhibitors

	α_1-Adrenergic Antagonists	5α-Reductase Inhibitors
Relaxes prostatic smooth muscle	Yes	No
Decreases prostate size	No	Yes
Halts disease progression	No	Yes
Peak onset	1–6 weeks	3–6 months
Efficacy	++	++ (for patients with enlarged prostates)
Frequency of dosing	1–2 times per day, depending on the agent and dosage formulation	Once per day
Decreases prostate-specific antigen	No	Yes
Sexual dysfunction adverse effects	+	++
Cardiovascular adverse effects	Yes	No

+ Motation is a quantitative assessment, for example 5α-reductase inhibitors cause more types of several dysfunction than α-adrenergic antagonists.

be measured before treatment begins, and the patient should have a digital rectal examination. After 6 months of therapy, the patient should have a repeat PSA. If the level does not decline by 50% and the patient has been adherent to the 5α-reductase inhibitor regimen, he should be evaluated for prostate cancer. Annually thereafter, the patient should have a PSA assay and digital rectal examination, and patients with an increase in PSA levels should be evaluated for prostate cancer or noncompliance to the prescribed regimen. To interpret a PSA level in a patient being treated with a 5α-reductase inhibitor, it is generally recommended that the actual measured level be doubled to get an estimate of the true level.[11,55]

CURRENT CONTROVERSY

Dutasteride is a nonselective 5α-reductase inhibitor that more quickly and effectively lowers intraprostatic DHT production and lowers plasma DHT levels than finasteride does. Whether these hormonal changes result in clinical advantages over finasteride remains to be elucidated.[47,48]

CURRENT CONTROVERSY

The combination of an α_1-adrenergic antagonist and 5α-reductase inhibitor can relieve LUTS, slow progression of BPH, and reduce the need for prostate surgery for patients with moderate to severe symptoms and a prostate of 40 g or larger. It may be possible to discontinue the α_1-adrenergic antagonist after the first several months; however, this potentially cost-saving measure requires further clinical study.

Combination Therapy

Combination therapy with an α_1-adrenergic antagonist and a 5α-reductase inhibitor is ideal for patients with severe symptoms, who also have an enlarged prostate gland of at least 40 g and PSA of at least 1.4 ng/mL (1.4 µg/L), a surrogate marker for an enlarged prostate gland.[6,11] Such patients appear to be at high risk for disease progression, as evidenced by symptom worsening and development of disease complications.[6] A regimen of finasteride and doxazosin for 5 years was shown to prevent symptom progression by 66%, decrease the risk of developing acute urinary retention by 81%, and decrease the need for prostate surgery by 67%.[6] In preliminary findings from a clinical trial of dutasteride versus tamsulosin versus the combination of dutasteride and tamsulosin for patients with large prostate glands (i.e., mean prostate volume of 55 ± 23 cc (55 ± 23 mL) and mean PSA of 4 ng/mL [4 mcg/L]), the combination drug regimen was more effective in reducing symptoms than dutasteride alone or tamsulosin alone. Whether the combination of dutasteride and tamsulosin prevents disease progression awaits long-term study results.[56] Although not proven by direct comparison trials, any combination of 5α-reductase inhibitor and α_1-adrenergic antagonist probably is similarly effective for patients with the aforementioned characteristics.[11] The disadvantages of a combination regimen include increased medication cost to the patient and an increased incidence of adverse drug effects (i.e., 18% to 27% of patients discontinued treatment due to hypotension).

Use of Anticholinergic Agents for Patients with BPH

Treatment with an α_1-adrenergic antagonist, 5α-reductase inhibitor, or surgery may improve urinary flow rate and bladder emptying; however, the patient may still complain of irritative voiding symptoms (e.g., urinary frequency, urgency), which mimic those of overactive bladder syndrome. Oxybutynin and tolterodine have been used to relieve these symptoms. By blocking muscarinic receptors in the detrusor muscle, these agents can reduce uninhibited detrusor contractions, a sequela of prolonged bladder outlet obstruction from BPH. Thus, they can reduce urinary frequency and urgency. Because elderly patients are sensitive to the central nervous system adverse effects and dry mouth associated with anticholinergic agents, patients should be started on the lowest effective dose and then slowly titrated up.[57–59] Similarly in the presence of BPH, anticholinergic agents can rarely cause acute urinary retention. Therefore, prescribing anticholinergic agents should be done cautiously, and patients monitored closely.

SURGICAL INTERVENTION

8 The gold standard for treatment of patients with complications of BPH is prostatectomy performed either transurethrally or as an open surgical procedure.[11,16] Surgical intervention is also used for patients with moderate to severe symptoms, who are not responsive to drug therapy, who are noncompliant with drug therapy, or who prefer surgical intervention. Surgical removal of the prostate offers the highest rate of symptom improvement, but it also has the highest complication rate.

With transurethral resection of the prostate (TURP), an endoscopic resectoscope inserted through the urethra is used to remove the inside core of the prostate. This enlarges the urethral opening at the bladder neck. TURP is performed only in men with enlarged prostates that are less than 50 g so that the resection can be completed in less than 1 hour. Often performed as outpatient surgery, this procedure produces on average a peak urinary flow rate increase of 125% and improvement of voiding symptoms by almost 90% in approximately 90% of patients.[16] A common complication of TURP is retrograde ejaculation, occurring in up to 75% of patients. Significant bleeding, urinary incontinence, and erectile dysfunction occur in smaller but significant numbers of patients (2% to 15%).[60,61] Approximately 2% to 10% and 12% to 15% of patients require second surgeries within 5 and 8 years, respectively.[60]

Men with larger prostates (>50 g) require an open surgical procedure (open prostatectomy), which can be performed retropubically or suprapubically. This necessitates hospitalization for at least a few days, anesthesia, and a longer recuperation time. Adverse effects of open prostatectomy include bleeding, urinary and soft-tissue infection, retrograde ejaculation in 77% of patients, erectile dysfunction in 16% to 33% of patients, and urinary incontinence in 2% of patients. The reoperation rate is 3% to 5% at 10 years.[11]

Transurethral incision of the prostate (TUIP) is an alternative surgical procedure for patients with moderate to severe voiding symptoms who have an enlarged prostate gland less than 30 g in size. In the short term TUIP is as effective as TURP but requires less operation time, causes less blood loss, and produces fewer adverse effects.[11] TUIP involves using an endoscopic resectoscope to make two or three incisions at the bladder neck to widen the opening. In limited long-term studies, the reoperation rate for TUIP is slightly higher than with TURP.

Minimally invasive surgical procedures are highly desirable by patients. The procedures are short (lasting minutes), have a lower potential to produce adverse effects, are less expensive than continuous drug therapy lasting years, and they may be particularly useful in debilitated patients who are poor surgical candidates. The ideal candidates have moderate to severe voiding symptoms with smaller sized prostate glands. These procedures typically use heat energy from microwaves, water, or laser to destroy prostate

tissue.[11,62] Commonly used procedures include transurethral needle ablation of the prostate and transurethral microwave thermotherapy of the prostate.[63] A disadvantage of all minimally invasive surgical procedures is that the percentage of patients who may develop acute urinary retention in the immediate postoperative period and may require reoperation after an initial improvement in symptoms is higher than that of patients who undergo TURP or open prostatectomy.[64]

PHYTOTHERAPY

9 Although phytotherapy is widely used in Europe for the management of BPH, the published data on herbal agents are largely inconclusive and conflicting. Studies often lack placebo controls, which are essential for assessing treatments of BPH because spontaneous regression of symptoms can occur. Furthermore, because these agents are marketed under the Dietary Supplements Health and Education Act, their efficacy, safety, and quality are not regulated by the FDA. For these reasons, herbal products—including saw palmetto berry (*Serenoa repens*), stinging nettle (*Urtica dioica*), South African stargrass (*Hypoxis rooperi*), pumpkin seed (*Cucurbita pepo*), and African plum (*Pygeum africanum*)—are not recommended for treatment of BPH.[11,65–68] An excellent review on phytotherapy for BPH has been published.[68]

EVALUATION OF THERAPEUTIC OUTCOMES

The primary therapeutic outcome of BPH therapy is improvement of voiding symptoms with minimal treatment-related adverse effects. As a disease for which therapy is directed at the voiding symptoms that the patient finds most bothersome, assessment of outcomes depends on the patient's perceptions of the effectiveness of therapy. Use of a validated, standardized instrument, such as the AUA Symptom Score, for assessing patient's voiding symptoms is important in this process.[11]

For patients being considered for surgical treatment, objective measures of bladder emptying are useful and include the urinary flow rate and PVR urine volume (see Diagnostic Evaluation above).

Because this patient population is at high risk for prostate cancer, PSA should be measured and a digital rectal examination performed annually if the patient has a life expectancy of at least 10 years. For patients taking 5α-reductase inhibitors, a second PSA taken after 6 months of treatment should be compared with baseline measurements. If the patient is suspected of having developed renal impairment as a consequence of long-standing bladder outlet obstruction, then BUN and serum creatinine should be evaluated at regular intervals.

SUMMARY

An ubiquitous disease of aging men, symptomatic BPH requires medical attention to preserve the patient's quality of life and to prevent disease complications, many of which can be life threatening in this patient population. In men who have no or mildly bothersome symptoms, watchful waiting and behavior modification are the best treatment approach, as BPH remains stable or even regresses in approximately half of these men.

For patients with voiding symptoms that are moderate to severely bothersome, pharmacotherapy is indicated. An α_1-adrenergic antagonist is the agent of first choice. Second-generation agents include terazosin, doxazosin, and alfuzosin, and third-generation agents include tamsulosin and silodosin. Immediate-release formulations of terazosin and doxazosin cause more cardiovascular adverse effects than do extended-release doxazosin or alfuzosin, tamsulosin, or silodosin. Whether extended-release doxazosin, extended-release alfuzosin, or silodosin are as well tolerated as tamsulosin for patients at risk for hypotension or hypotension-related morbidity remains to be elucidated. 5α-Reductase inhibitors are preferred drug treatment for patients with enlarged prostates who poorly tolerate the hypotensive adverse effects of α_1-adrenergic antagonists. However, 5α-reductase inhibitors have a slow onset of action. For patients who do not respond to monotherapy, combination drug therapy could be attempted. Such regimens have been found to be most effective for patients with enlarged prostates greater than 40 g. Alternatively, surgery is an option.

For patients who have complications of BPH, surgery is required. Although it has more adverse complications than does pharmacotherapy or watchful waiting, TURP is considered the gold standard.

ABBREVIATIONS

AUA: American Urological Association

BPH: benign prostatic hyperplasia

BUN: blood urea nitrogen

DHT: dihydrotestosterone

LUTS: lower urinary tract symptoms

PSA: prostate-specific antigen

PVR: postvoid residual

TUIP: transurethral incision of the prostate

TURP: transurethral resection of the prostate

CHAPTER 94

Urinary Incontinence

ERIC S. ROVNER, JEAN WYMAN, THOMAS LACKNER, AND DAVID R.P. GUAY

KEY CONCEPTS

1. In evaluating urinary incontinence, drug-induced or drug-aggravated etiologies must be ruled out.
2. Accurate diagnosis and classification of urinary incontinence type are critical to the selection of appropriate pharmacotherapy.
3. Nonpharmacologic, nonsurgical therapy is the cornerstone of management of several types of urinary incontinence, often should be the first therapy initiated, and should be continued even when drug therapy is initiated.
4. Anticholinergic/antispasmodic agents are the pharmacologic therapies of choice for bladder overactivity (urge incontinence).
5. Duloxetine (not approved for treatment of urinary incontinence in the United States), α-adrenergic receptor agonists, and topical (vaginal) estrogens (alone or together) are the pharmacologic therapies of choice in urethral underactivity (stress incontinence).
6. Patient-specific treatment goals should be identified. They are not static and may change over time. Choice of therapy may be influenced by characteristics such as patient age, comorbidities, concurrent medications, and ability to adhere to the prescribed regimen. If therapeutic goals are not achieved with a given agent at optimal dosage, addition of a second agent or switching to an alternative single agent should be considered.

Urinary incontinence (UI) is defined as involuntary leakage of urine.[1] It is frequently accompanied by other bothersome lower urinary tract symptoms, such as urgency, increased daytime frequency, and nocturia. It is a common yet underdetected and underreported health problem that can significantly affect quality of life. Patients with UI may have depression as a result of the perceived lack of self-control, loss of independence, and lack of self-esteem, and they often curtail their activities for fear of an "accident." UI may also have serious medical and economic ramifications for untreated or undertreated patients, including perineal dermatitis, worsening of pressure ulcers, urinary tract infections, and falls.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

This chapter highlights the epidemiology, etiology, pathophysiology, and treatment of stress, urge, mixed, and overflow UI in men and women.

EPIDEMIOLOGY

Determining the true prevalence of UI is difficult because of problems with definition, reporting bias, and other methodologic issues.[2] Epidemiologic studies have not historically used a standard definition of the condition or a standard methodology for data recording, with some studies including "postvoid dribbling," while other studies specify "urinary leakage causing a social or hygienic problem." Many people suffer from UI, and the impact of this condition is substantial, crossing all racial, ethnic, and geographic boundaries. Compared with continent controls, patients with UI have an overall poorer quality of life.[3] Several studies have objectively shown that UI is associated with reduced levels of social and personal activities, increased psychological distress, and overall decreased quality of life as measured by numerous indices.[4,5] The condition can affect people of all age groups, but the peak incidence of UI, at least in women, appears to occur around the age of menopause, with a slight decrease in the age group 55 to 60 years, and then a steadily increasing prevalence after age 65 years.

One of the earliest comprehensive epidemiologic studies on UI was conducted by Diokno et al.[6] using a standardized survey questionnaire. The Medical, Epidemiologic, and Social Aspects of Aging survey found that the prevalence of UI in noninstitutionalized women 60 years of age and older was approximately 38%. Almost one third of those surveyed noted urine loss at least once weekly, and 16% noted UI daily. A publication from a National Institutes of Health working group conference estimated the median level of UI prevalence to be approximately 20% to 30% during young adult life, with a broad peak around middle age (30%–40% prevalence) and an increase in the elderly (30%–50% prevalence).[7]

In the United States, chronic UI is one of the most common reasons cited for institutionalization of the elderly, and the condition is frequently encountered in the nursing home setting.[8] Little is known about the basic differences in clinical and epidemiologic characteristics of incontinence across racial or ethnic groups. Some studies report a higher incidence of UI overall in white populations[9,10] as compared with African Americans, but differences in access to healthcare as well as cultural attitudes and mores may contribute to these differences.

Consistent across all studies of unselected, noninstitutionalized populations is that UI is at least half as common in men as in women.[11,12] Overall, the prevalence of UI in men has been estimated to be approximately 9%.[13] Unlike in women, the prevalence of UI in men increases with age across most studies, with the highest prevalence recorded in the oldest patient cohorts.[13]

ETIOLOGY AND PATHOPHYSIOLOGY

ANATOMY

The lower urinary tract consists of the bladder, urethra, urinary or urethral sphincter, and surrounding musculofascial structures, including connective tissue, nerves, and blood vessels. The urinary bladder is a hollow organ composed of smooth muscle and connective tissue located deep in the bony pelvis in men and women. The urethra is a hollow tube that acts as a conduit for urine flow out of the bladder. The interior surface of both the bladder and the urethra is lined by an epithelial cell layer termed the *transitional epithelium*, which is in constant contact with urine. Previously considered inert and inactive, transitional epithelium may play an active role in the pathophysiology of many lower urinary tract disorders, including interstitial cystitis and UI.[14] The urinary or urethral sphincter is a combination of smooth and striated muscle within and surrounding the most proximal portion of the urethra adjacent to the bladder in both men and women. This is a functional but not anatomic sphincter that includes a portion of the bladder neck or outlet as well as the proximal urethra.

URINARY CONTINENCE

To prevent incontinence during the bladder filling and storage phase of the micturition cycle, the urethra, or more accurately the urethral sphincter, must maintain adequate closure in order to resist the flow of urine from the bladder at all times until voluntary voiding is initiated. Urethral closure or resistance to flow is maintained to a large degree by the proximal (under involuntary control) and distal (under both voluntary and involuntary control) urinary sphincters, a combination of smooth and striated muscles within and external to the urethra. Variable contributions to urethral closure may also come from the urethral mucosa, submucosal spongy tissue, and the overall length of the urethra. During bladder filling and storage, the bladder accommodates increasing volumes of urine flowing in from the upper urinary tract without a significant increase in bladder (intravesical) pressure. The maintenance of a low intravesical pressure despite increasing volumes of urine is a unique property of the bladder and is termed *compliance*. In addition, bladder or detrusor smooth muscle activity is normally suppressed during the filling phase by centrally mediated neural reflexes. Normal bladder emptying occurs with opening of the urethra concomitant with a volitional bladder contraction. Bladder contraction occurs in a coordinated fashion, resulting in a rise in intravesical pressure. The rise in intravesical pressure is ideally of adequate magnitude and duration to empty the bladder to completion. Opening and funneling of the bladder outlet results in urine flow into the urethra until the bladder is emptied to near completion.

The primary motor input to the detrusor muscle of the bladder is along the pelvic nerves emanating from spinal cord segments S2 to S4. Parasympathetic impulses travel to the bladder along the efferent fibers of the pelvic nerves. The impulses pass through ganglia situated in the bladder wall before reaching their target. Acetylcholine appears to be the primary neurotransmitter at the neuromuscular junction in the human lower urinary tract. Both volitional and involuntary contractions of the detrusor muscle are mediated by activation of postsynaptic muscarinic receptors by acetylcholine. Of the five known subtypes of muscarinic receptors, the majority of bladder smooth muscle cholinergic receptors are of the M_2 variety. In humans, the ratio of M_2/M_3 receptor numbers is approximately 3:1. However, M_3 receptors are the subtype responsible for both emptying contractions of normal micturition as well as involuntary bladder contractions that may result in UI.[15] Thus most pharmacologic antimuscarinic therapy is primarily anti-M_3 based.

This description of the mechanisms of urinary continence is a bit simplistic. Many other neurohumoral pathways and mechanisms, both within and outside the urinary tract, may play substantial roles in urinary continence (and voiding dysfunction) and may be future therapeutic options for treatment of voiding dysfunction and UI. Examples include adrenergic, purinergic, serotoninergic, and dopaminergic pathways, tachykinin receptor antagonists, and calcium and potassium channel modulators.[15]

The bladder and urethra normally operate in unison during the bladder filling and storage phase, as well as the bladder emptying phase of the micturition cycle. The smooth and striated muscles of the bladder and urethra are organized during the micturition cycle by a number of reflexes coordinated at the pontine micturition center in the midbrain. Disturbances in the neural regulation of micturition at any level (brain, spinal cord, or pelvic nerves) often lead to characteristic changes in lower urinary tract function that may result in UI.[16]

Mechanisms of Urinary Incontinence

Simply stated, UI may occur as a result of abnormalities of only the urethra (including the bladder outlet and urinary sphincter) or only the bladder or as a combination of abnormalities in both.[17] Abnormalities may result in either overfunction or underfunction of the bladder and/or urethra, with resulting development of UI. Although this simple classification scheme excludes extremely rare causes of UI such as congenital ectopic ureters and urinary fistulas, it is useful for gaining a working understanding of the condition.

Urethral Underactivity (Stress Urinary Incontinence) Some patients characteristically note UI during exertional activities such as exercise, running, lifting, coughing, and sneezing. This implies that the compromised urethral sphincter is no longer able to resist the flow of urine from the bladder during periods of physical activity. In essence, increases in intraabdominal pressure during physical activity are transmitted to the bladder (an intraabdominal organ), compressing it and forcing urine through the weakened sphincter.

This type of UI is known as *stress urinary incontinence* (SUI). Although the exact etiology of urethral underactivity and SUI in women is incompletely understood, clearly identifiable risk factors include pregnancy, childbirth, menopause, cognitive impairment, obesity, and age.[18,19] The prevalence of SUI in women appears to peak during or after the onset of menopause. This implies that hormonal factors are important in maintaining continence.

In men, SUI is most commonly the result of prior lower urinary tract surgery or injury, with resulting compromise of the sphincter mechanism within and external to the urethra. Radical prostatectomy for treatment of adenocarcinoma of the prostate is probably the most common setting in which surgical manipulation leads to UI. Overall, SUI in the male is uncommon and, in the absence of prior prostate surgery, severe trauma, or neurologic illness, is extraordinarily rare. Transurethral resection of the prostate for benign prostatic hyperplasia (BPH; see Chap. 93) may lead to SUI in men.

Bladder Overactivity (Urge Urinary Incontinence) Bladder overactivity may occur during bladder filling and urine storage due to involuntary bladder (detrusor) contractions. Symptoms of bladder overactivity occur because the detrusor muscle is overactive and contracts inappropriately during the filling phase which, in the neurologically normal individual, results in a sense of urinary urgency. The terms *overactive bladder* and *detrusor overactivity* are distinct and should not be used interchangeably, as they frequently are. The International Continence Society defines overactive bladder as a symptom syndrome characterized by urinary urgency, with frequency and nocturia, with/without associated UI in the absence of a known pathologic condition that may result in similar symptoms

(e.g., urinary tract infection, bladder cancer).[1] When UI occurs concomitantly with a sense of urinary urgency, it is termed urge urinary incontinence (UUI).[1] The latter is most commonly, although not invariably, associated with involuntary detrusor contractions.

Therefore, a diagnosis of overactive bladder does not require urodynamic testing for confirmation but is a diagnosis based on patient symptoms. Conversely, detrusor overactivity is a specific urodynamic diagnosis referring to the finding of involuntary detrusor contractions during the filling phase of a urodynamic study. Therefore, invasive urodynamic testing is required to make the diagnosis. Up to 40% of patients with overactive bladder do not demonstrate detrusor overactivity on urodynamic testing. The clinical significance of this finding is unknown. However, the effectiveness of pharmacologic therapy appears to be independent of the presence or absence of detrusor overactivity.[20] This distinction between overactive bladder (a symptom syndrome) and detrusor overactivity (a urodynamic diagnosis) is essential in fully understanding the patient population under study and the effects of pharmacologic therapy reported in the literature.

Symptoms characteristic of overactive bladder are urinary frequency and urgency, with or without urge incontinence. *Frequency* is defined as micturition more than eight times per day. *Urgency* is described as a sudden compelling desire to urinate that is difficult to delay.[1] People suffering from overactive bladder typically have to empty their bladder frequently, and, when they experience a sensation of urgency, they may leak urine if they are unable to reach the toilet quickly. Many patients have associated nocturia (>1 micturition per night) and/or nocturnal incontinence (enuresis). Nocturia and enuresis are particularly disruptive to sleep. For patients with incontinence, the amount of urine lost may be large, as the bladder may empty completely.

Most patients with overactive bladder and UUI have no identifiable underlying etiology and thus are classified as "idiopathic." Patients with a relevant neurologic condition and with urinary incontinence related to involuntary bladder contractions demonstrated on urodynamic testing are classified as having neurogenic detrusor overactivity. Clearly identifiable risk factors for UUI include normal aging, neurologic disease (including stroke, Parkinson's disease, multiple sclerosis, and spinal cord injury), and bladder outlet obstruction (e.g., due to BPH or prostate cancer).

The mechanism for overactive bladder and UUI must be either neurogenic or myogenic. The neurogenic hypothesis ascribes the condition to disease-related changes within the central or peripheral nervous systems.[21] The myogenic hypothesis states that overactive bladder and UUI result from changes within the smooth muscle of the bladder wall itself.[22] Precipitating factors, such as bladder outlet obstruction (BOO), can cause partial denervation of smooth muscle, leading to a state of decreased responsiveness to activation of intrinsic nerves but supersensitivity to contractile agonists and direct electrical activation and detrusor overactivity.[23] Indeed, overactive detrusor muscle from an individual with BOO may or may not be quite different as compared with the same muscle tissue from an individual with idiopathic or neurogenic detrusor overactivity in terms of many physiologic and anatomic characteristics (including receptor type[s] and density/densities, collagen content, and innervation).[24] A full discussion of these differences is beyond the scope of this chapter. Thus, in practice, UUI is difficult to categorize as either neurogenic or myogenic in origin, as these etiologies often seem to be interconnected and complementary.

Urethral Overactivity and/or Bladder Underactivity (Overflow Incontinence) Overflow incontinence, the result of urethral overactivity and/or bladder underactivity, is an important but uncommon type of UI in both men and women. Overflow incontinence results when the bladder is filled to capacity at all times but is unable to empty, causing urine to leak from a distended bladder past a normal or even overactive outlet and sphincter.

In the setting of urethral overactivity, resistance to the flow of urine during volitional voiding is increased, resulting in functional or anatomic obstruction and incomplete bladder emptying. Clinically and practically, the most common causes of urethral overactivity in men are anatomic urethral obstruction, including that due to BPH and prostate cancer. In women, urethral overactivity is rare but may result from cystocele formation (with resultant kinking or obstruction of the urethra) or surgical overcorrection (iatrogenic obstruction) following anti-SUI surgery. In both men and women, overflow UI may be associated with systemic neurologic dysfunction or diseases, such as spinal cord injury or multiple sclerosis.

Bladder underactivity may result in overflow incontinence. Under certain circumstances, the detrusor muscle of the bladder may become progressively weakened and eventually lose the ability to voluntarily contract. In the absence of adequate contractility, the bladder is unable to empty completely, and large volumes of residual urine are left after micturition. Both myogenic and neurogenic factors have been implicated in producing the impaired contractility seen in this condition. Clinically, overflow incontinence is most commonly seen in the setting of long-term chronic bladder outlet obstruction in men, such as that due to BPH or prostate cancer, diabetes mellitus, or denervation due to radical pelvic surgery, such as abdominopelvic resection or radical hysterectomy.

Mixed Incontinence and Other Types of Urinary Incontinence Various types of UI may coexist in the same patient. The combination of bladder overactivity and urethral underactivity is termed *mixed incontinence*. The diagnosis is often difficult because of the confusing array of presenting symptoms. Bladder overactivity may also coexist with impaired bladder contractility. This occurs most commonly in the elderly and is termed *detrusor hyperactivity with impaired contractility*.[25]

Functional incontinence is not caused by bladder- or urethra-specific factors. Rather, in patients with conditions such as dementia or cognitive or mobility deficits, the UI is linked to the primary disease process more than any extrinsic or intrinsic deficit of the lower urinary tract. An example of functional incontinence occurs in the postoperative orthopedic surgery patient. Following extensive orthopedic reconstructions such as total hip arthroplasty, patients are often immobile secondary to pain or traction. Therefore, patients may be unable to access toileting facilities in a reasonable amount of time and may become incontinent as a result. Treatment of this type of UI may involve simple interventions such as placing a urinal or commode at the bedside that allows for uncomplicated access to toileting.

Many localized or systemic illnesses may result in UI because of their effects on the lower urinary tract or the surrounding structures:

- Dementia/delirium
- Depression
- Urinary tract infection (cystitis)
- Postmenopausal atrophic urethritis or vaginitis
- Diabetes mellitus
- Neurologic disease (e.g., stroke, Parkinson's disease, multiple sclerosis, spinal cord injury)
- Pelvic malignancy
- Constipation
- Congenital malformations

1 Many commonly used medications may precipitate or aggravate existing voiding dysfunction and UI (Table 94–1).

TABLE 94-1 Medications That Influence Lower Urinary Tract Function

Medication	Effect
Diuretics, acetylcholinesterase inhibitors	Polyuria, frequency, urgency
α-Receptor antagonists	Urethral relaxation and stress urinary incontinence in women
α-Receptor agonists	Urethral constriction and urinary retention in men
Calcium channel blockers	Urinary retention
Narcotic analgesics	Urinary retention from impaired contractility
Sedative hypnotics	Functional incontinence caused by delirium, immobility
Antipsychotic agents	Anticholinergic effects and urinary retention
Anticholinergics	Urinary retention
Antidepressants, tricyclic	Anticholinergic effects, α-antagonist effects
Alcohol	Polyuria, frequency, urgency, sedation, delirium
Angiotensin-converting enzyme inhibitors (ACEIs)	Cough as a result of ACEIs may aggravate stress urinary incontinence by increasing intraabdominal pressure

CLINICAL PRESENTATION

2 UI may present in a number of ways, depending on the underlying pathophysiology. Generally, SUI is considered the most common type of UI and probably accounts for at least a portion of UI in more than half of all incontinent women. Some studies have found that mixed UI (SUI + UUI) is the most common type of UI.[6] However, the proportions of SUI versus UUI versus mixed UI vary considerably with age group and sex of patients studied, study methodology, and a variety of other factors. A complete medical history, including an assessment of symptoms and a physical examination, is essential for correctly classifying the type of incontinence and thereby assuring appropriate therapy.

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO URETHRAL UNDERACTIVITY

General

- The patient usually notes UI during activities such as exercise, running, lifting, coughing, and sneezing. Occurs much more commonly in women (seen only in men with lower urinary tract surgery or injury compromising the sphincter).

Symptoms

- Urine leakage with physical activity (volume is proportional to activity level). No UI with physical inactivity, especially when supine (no nocturia). May develop urgency and frequency as a compensatory mechanism (or as a separate component of bladder overactivity).

Diagnostic Tests

- Observation of urethral meatus while patient coughs or strains.

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO BLADDER OVERACTIVITY

General

- Can have bladder overactivity and UI without urgency if sensory input from the lower urinary tract is absent.

Symptoms

- Urinary frequency (>8 micturitions per day), urgency with or without urge incontinence; nocturia (≥1 micturition per night) and enuresis may be present.

Diagnostic Tests

- Urodynamic studies are the gold standard for diagnosis. Urinalysis and urine culture should be negative (rule out urinary tract infection as the cause of frequency).

CLINICAL PRESENTATION OF URINARY INCONTINENCE RELATED TO URETHRAL OVERACTIVITY AND/OR BLADDER UNDERACTIVITY

General

- Important but rare type of UI in both men and women. Urethral overactivity is usually due to prostatic enlargement (males) or cystocele formation or surgical overcorrection following stress incontinence surgery in women.

Symptoms

- Lower abdominal fullness, hesitancy, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency. Abdominal pain if acute urinary retention is present.

Signs

- Increased postvoid residual urine volume.

Diagnostic Tests

- Digital rectal examination or transrectal ultrasound to rule out prostatic enlargement. Renal function tests to rule out renal failure due to acute urinary retention.

URINE LEAKAGE

UI represents a spectrum of severity in terms of both volume of leakage and degree of bother to the patient. To carefully consider the level of patient discomfort when discussing urine leakage, the clinician must probe during the patient interview to accurately determine the precise nature of the problem.

Use of absorbent products, such as panty liners, pads, or briefs, is an obvious point of discussion, but the clinician must keep in mind that use of these products varies among patients. The number and type of pads may not relate to the amount or type of incontinence, as their use is a function of personal preference and hygiene. A high number of absorbent pads may be used every day by a patient with severe, high-volume UI or, alternatively, by a fastidiously hygienic patient with low-volume leakage who simply changes pads often to prevent wetness or odor. Nevertheless, a large number of pads that are described by the patient as "soaked" is indicative of high-volume urine loss.

Regardless of the volume of urine loss, the desire to seek evaluation and therapy for UI in all patients is almost always elective and contingent on the degree of bother to the individual patient. As with the use of absorbent products, patients differ with regard to the amount of urine loss they will tolerate before considering the condition bothersome enough to seek assistance.

SYMPTOMS

Under the best of circumstances, UI is difficult to categorize based on symptoms alone (Table 94–2).[26] In a study of patients who appeared to have SUI based on symptoms and patient history,

TABLE 94-2 Differentiating Bladder Overactivity from Urethral Underactivity

Symptoms	Bladder Overactivity	Urethral Underactivity
Urgency (strong, sudden desire to void)	Yes	Sometimes
Frequency with urgency	Yes	Rarely
Leaking during physical activity (e.g., coughing, sneezing, lifting)	No	Yes
Amount of urinary leakage with each episode of incontinence	Large if present	Usually small
Ability to reach the toilet in time following an urge to void	No or just barely	Yes
Nocturnal incontinence (presence of wet pads or undergarments in bed)	Yes	Rare
Nocturia (waking to pass urine at night)	Usually	Seldom

urodynamics showed that only 72% of patients had SUI as the sole cause of incontinence.[27]

Patients with urethral underactivity or SUI characteristically complain of urinary leakage with physical activity. Volume of leakage is proportional to the level of activity. They will often leak urine during periods of exercise, coughing, sneezing, lifting, or even when rising from a seated to a standing position. Patients with pure SUI will not have leakage when physically inactive, especially when they are supine. Often they will have little or no UI at night, will not awaken to void during the night (nocturia), will not wet the bed, and often do not even wear absorbent products during the night. Urinary urgency and frequency may be associated with SUI, either as a separate component caused by bladder overactivity (mixed incontinence) or as a compensatory mechanism wherein the patient with SUI learns to toilet frequently to prevent large-volume urine loss during physical activity.

Typical symptoms of bladder overactivity include frequency, urgency, and urge incontinence. Nocturia and nocturnal incontinence are often present. Urine leakage is unpredictable, and the volume loss may be large. Patients often wear protection both day and night. Urinary frequency can be affected by a number of factors unrelated to bladder overactivity, including excessive fluid intake (polydipsia) and bladder hypersensitivity states such as interstitial cystitis and urinary tract infection, and should be ruled out. In some patients, bladder overactivity manifests as UI without awareness in the absence of a sense of urinary urgency or frequency. *Urinary urgency*, a sensation of impending micturition, requires intact sensory input from the lower urinary tract. In patients with spinal cord injury, sensory neuropathies, and other neurologic diseases, a diminished ability to perceive or process sensory input from the lower urinary tract may result in bladder overactivity and UI without urgency or urinary frequency. When bladder contraction occurs without warning and sensation is absent, the condition is referred to as *reflex incontinence*.

Patients with overflow incontinence may present with lower abdominal fullness as well as considerable obstructive urinary symptoms, including hesitancy, straining to void, decreased force of urinary stream, interrupted stream, and a vague sense of incomplete bladder emptying. These patients may also have a significant component of urinary frequency and urgency. In patients with acute urinary retention and overflow incontinence, lower abdominal pain may be present. Although these symptoms are not specific for overflow incontinence, they may warrant further investigation, including an assessment of postvoid residual urine volume.

SIGNS

A presenting complaint of UI mandates a directed physical examination and a brief neurologic assessment. The workup ideally includes an abdominal examination to exclude a distended bladder, neurologic assessment of the perineum and lower extremities, pelvic examination in women (looking especially for evidence of prolapse or hormonal deficiency), and genital and prostate examination in men.

SUI can usually be objectively demonstrated by having the patient cough or strain during the examination and observing the urethral meatus for a sudden spurt of urine. In women, SUI may be associated with varying degrees of vaginal prolapse, including cystourethrocele (bladder and urethral prolapse), enterocele (small bowel prolapse), rectocele (rectal prolapse), and uterine prolapse. These conditions may have important implications for therapy in that treatment of the prolapse may result in improvement of urinary symptoms.

Perineal skin maceration, erythema, breakdown, and ulceration may be indicative of chronic, severe UI. Patients with chronic incontinence may manifest fungal infections of the skin of the perineum and upper thighs.

In both men and women, digital rectal examination provides an opportunity to check ambient rectal tone and the integrity of the sacral reflex arc (e.g., anal wink) as well as assess the patient's ability to perform a voluntary pelvic floor muscle contraction (i.e., Kegel exercise), which may be an important factor in deciding on appropriate therapy. In men, a digital examination of the prostate assesses for the presence of prostate cancer, inflammation, and BPH.

A targeted neurologic examination includes assessment of reflexes, rectal tone, and sensory or motor deficits in the lower extremities, which might be indicative of systemic or localized neurologic disease. Neurologic diseases have the potential to affect bladder and sphincter function and thus may have significant implications in the incontinent patient.

PRIOR MEDICAL OR SURGICAL ILLNESS

UI may present in the setting of concurrent, seemingly unrelated illnesses. New-onset UI may be the initial manifestation of systemic illnesses such as diabetes mellitus, metastatic malignancies, multiple sclerosis, and other neurologic illnesses. Central nervous system disease, or injury above the level of the pons, generally results in symptoms of bladder overactivity and UUI. Spinal cord injury or disease may manifest as bladder overactivity and UUI or as overflow incontinence, depending on the spinal level and completeness of the injury or disease.

Medications may have wide-ranging effects on lower urinary tract function (see Table 94–1). A thorough inquiry into the use of new medications in the setting of recent-onset UI may show a relationship.

Acute UI manifesting in the immediate postoperative setting may be secondary to a number of factors, including surgical manipulation and immobility, and to a number of medications, especially opioid analgesics. In the postoperative setting, acute urinary retention and overflow incontinence are commonly related to the administration of anesthetic agents and/or opioid analgesics in the perioperative period. These agents may have profound effects on bladder contractility that are completely reversible once the agents are metabolized and excreted.

Prior surgery may have effects on lower urinary tract function. UI following prostate surgery in men is highly suggestive of injury to the sphincter and resultant SUI. Pelvic surgery for benign and malignant conditions may result in denervation or injury to the lower urinary tract. This includes bowel surgery and gynecologic procedures. For example, new-onset total UI following gynecologic surgery suggests intraoperative bladder injury and subsequent development of a postoperative vesicovaginal fistula. Radiation therapy to the pelvis for malignant disease (e.g., prostate cancer or

cervical cancer) may result in injury to the bladder or urethra and subsequent UI.

In women, UI may be related to several gynecologic factors, including childbirth, hormonal status, and prior gynecologic surgery. Pregnancy and childbirth, particularly vaginal delivery, are associated with SUI and pelvic prolapse. Significant SUI in the nulliparous woman is uncommon. UI that becomes progressive at or around menopause suggests a hormonal component that may be responsive to estrogen or hormone replacement therapy.

UI may present in the setting of other significant pelvic floor disorders, signs, and symptoms. Constipation, diarrhea, fecal incontinence, dyspareunia, sexual dysfunction, and pelvic pain may be related to UI. A history of gross hematuria in the setting of UI mandates further urologic investigation, including radiologic imaging of the upper urinary tract and cystoscopy. Acute dysuria with or without hematuria in the setting of UI suggests cystitis. Urinalysis and urine culture should be performed in these patients.

TREATMENT

Urinary Incontinence

NONPHARMACOLOGIC TREATMENT

3 Nonpharmacologic treatment of UI is recommended as the first line of therapy at a primary care level. For patients in whom pharmacologic or surgical management is inappropriate or undesired, nondrug treatment is the only option. Examples of patients who fulfill these criteria include patients who are not medically fit for surgery, those who plan future pregnancies (which may adversely affect long-term surgical outcomes), those with overflow incontinence whose condition is not amenable to surgery or drug therapy, those with comorbid conditions that place them at high risk for adverse effects from drug therapy, those who are delaying surgery or do not want to undergo surgery, and those with mild to moderate symptoms who do not want to take medication.

For additional information on nonpharmacologic interventions for UI, readers are referred to comprehensive literature reviews and consensus opinions of treatment guidelines on nonpharmacologic interventions by multidisciplinary experts.[28] Table 94–3 summarizes the basic nondrug approaches.

Behavioral interventions are the first line of treatment for SUI, UUI, and mixed UI. Interventions include lifestyle modifications, toilet scheduling regimens, and pelvic floor muscle rehabilitation. Because the key to success with any type of behavioral intervention is motivation of patients or caregivers, these individuals must be active participants in developing a treatment plan. Regular follow-up is needed to help motivate patients and caregivers, provide reassurance and support, and monitor treatment outcomes.

PHARMACOLOGIC TREATMENT

Urge Urinary Incontinence

Pharmacotherapy is useful when UUI symptoms are not adequately controlled with nonpharmacologic therapies, particularly in patients with low functional bladder capacity, especially individuals who frequently attempt to toilet and are independent or require only limited assistance in toileting. In many cases, the combined use of pharmacotherapy with nonpharmacologic therapy produces a better response than either intervention alone.

4 Anticholinergic/antispasmodic drugs have proved to be the most effective agents for suppressing premature detrusor contractions, enhancing bladder storage, and relieving UUI symptoms and complications and constitute the pharmacotherapy of first choice for treatment of UUI (Tables 94–4 and 94–5).[29–48] Drugs with anticholinergic activity act by antagonizing muscarinic cholinergic receptors, through which efferent parasympathetic nerve impulses evoke detrusor contraction. Anticholinergics have been demonstrated to improve quality of life, with no significant differences between agents.[49] Women with mixed UI or UUI plus urethritis or vaginitis may benefit from a topical estrogen (alone or in combination with an anticholinergic drug). Patients with irritative symptoms of BPH that persist despite specific BPH treatment may benefit from anticholinergic therapy as well (caution is warranted because these agents may precipitate acute urinary retention).

Immediate-Release Oxybutynin Even though a substantial proportion of patients may discontinue oxybutynin immediate-release (IR) therapy because of its nonurinary antimuscarinic effects, oxybutynin IR remains the drug of first choice for treatment of UUI and the gold standard against which other drugs are compared. In addition to antimuscarinic effects (e.g., dry mouth, constipation, vision impairment, confusion, cognitive dysfunction, and tachycardia), oxybutynin IR is associated with orthostatic hypotension secondary to α-adrenergic receptor blockade as well as sedation and weight gain from histamine H_1-receptor blockade.[30,35,50–54] Furthermore, adverse effects jeopardize medication adherence and can prevent dose escalation to that needed for optimal benefit.

Emerging evidence suggests that the high incidence of adverse effects, especially dry mouth, with use of oxybutynin IR is largely due to the active metabolite *N*-desethyloxybutynin (DEO), which is generated during extensive first-pass metabolism in the liver and upper gastrointestinal tract.[55] The lower DEO plasma concentrations seen with long-acting forms of oxybutynin (which are due to reduced first-pass metabolism) compared with those of oxybutynin IR may explain the lesser propensity of the long-acting formulations to cause dry mouth and other anticholinergic adverse effects.

Another factor associated with the adverse effects of oxybutynin IR, especially in older patients, is the transient high peak serum oxybutynin plasma concentrations.[56] Oxybutynin IR is best tolerated when the dose is gradually escalated from no more than 2.5 mg twice daily to start, to 2.5 mg three times daily after 1 month, then further increased in increments of 2.5 mg/day every 1 to 2 months until the desired response or the maximum recommended or tolerated dose is attained. The optimal response usually requires no more than 5 mg three times daily (see Table 94–4).[30,57]

Adverse effects of oxybutynin IR can sometimes be managed by a dose reduction if this does not significantly compromise drug efficacy. Dry mouth can be relieved by use of sugarless hard candy, gum, or a saliva substitute. Constipation can be minimized by increasing the intake of water, dietary fiber, physical activity such as walking, or laxative therapy. The need for multiple daily dosing of oxybutynin IR can further jeopardize adherence, especially in people who take multiple medications or those who are cognitively impaired.

Extended-Release Oral Oxybutynin Because of the problems noted with oxybutynin IR, an extended-release (XL) formulation of oxybutynin was developed. It can be considered an alternative first-line therapy of UUI.[58]

Unlike oxybutynin IR, oxybutynin XL delivers a controlled amount of oxybutynin continuously throughout the gastrointestinal tract over a 24-hour period, reducing first-pass metabolism by cytochrome P450 (CYP) isoenzyme 3A4, which is present in higher concentrations in the upper portion of the small intestine than in the lower gastrointestinal tract.[58,59] This results in relative bioavailabilities of oxybutynin and DEO of 153% and 69%, respectively, for oxybutynin XL compared with oxybutynin IR.[60] The greater ratio of parent drug concentration to active metabolite concentration after

TABLE 94-3 Nonpharmacologic Management of Urinary Incontinence

Intervention	Description	Patient Characteristics
Lifestyle modifications	Self-management strategies targeted toward reducing or eliminating risk factors that cause or exacerbate urinary incontinence	Smoking cessation, weight reduction for obese patients with stress and urge incontinence, constipation prevention, caffeine reduction, fluid modification only for those with abnormally high fluid intake
Scheduling regimens		
Timed voiding	Toileting on a fixed schedule where interval does not change, typically every 2 hours during waking hours	Used for stress, urge, and mixed incontinence in patients with cognitive or physical impairments; used in patients without impairments who have infrequent voiding patterns
Habit retraining	Scheduled toiletings with adjustments of voiding intervals (longer or shorter) based on patient's voiding pattern	Used for institutionalized or homebound patients with cognitive or physical impairments; may be used in patients who have diuretic-induced incontinence
Prompted voiding	Scheduled toiletings that require prompts to void from a caregiver, typically every 2 hours; patient assisted in toileting only if response is positive; used in conjunction with operant conditioning techniques for rewarding patients for maintaining continence and appropriate toileting	Used for patients who are functionally able to use toilet or toilet substitute, able to feel urge sensation, and able to request toileting assistance appropriately; primarily used in institutional settings or in homebound patients with an available caregiver
Bladder training	Scheduled toiletings with progressive voiding intervals; includes teaching urge suppression strategies using relaxation and distraction techniques, self-monitoring, and use of reinforcement techniques; sometimes combined with drug therapy	Used for stress, urge, and mixed incontinence in patients who are cognitively intact, able to toilet, and motivated to comply with training program
Pelvic floor muscle rehabilitation		
Pelvic floor muscle exercises (e.g., Kegel exercises)	Regular practice of pelvic floor muscle contractions; may involve use of pelvic floor muscle contraction for prevention of stress leakage and urge inhibition	Used for stress, urge, and mixed incontinence in patients who can correctly contract pelvic floor muscles without using accessory muscles; requires cognitively intact and highly motivated patient
Biofeedback	Use of electronic or mechanical instruments to display visual or auditory information about neuromuscular or bladder activity; used to teach correct pelvic floor muscle contraction and/or urge inhibition; home trainers are available (e.g., Myself, DesChutes Medical Products, Bend, OR; Pathway MR-10 or MR-20, Prometheus Group, Dover, NH)	Used for stress, urge, and mixed incontinence in patients who have the capability to learn voluntary control through observation and are motivated; used in conjunction with pelvic floor muscle exercises
Vaginal weight training	Active retention of increasing vaginal weights (e.g., Step Free Weights, Medgo LLC, Venice, FL); typically used in combination with pelvic floor muscle exercises at least twice per day	Women with stress incontinence who are cognitively intact, can correctly contract pelvic floor muscles, able to stand, and have sufficient vaginal vault and introitus to retain cone, and are highly motivated; contraindicated in patients with moderate to severe pelvic organ prolapse
Acupuncture	Involves insertion of disposable sterile fine stainless steel needles into points on the skin that are thought to suppress or stimulate spinal and/or supraspinal reflexes to the bladder and/or urethra	Used for urge and mixed incontinence and urinary incontinence due to spinal cord injury
Nonimplantable electrical stimulation	Application of electrical current through vaginal, anal, surface, or fine needle electrodes; used to inhibit bladder overactivity and improve awareness, contractility, and efficacy of pelvic floor muscle contraction; hand-held stimulators for home use are available (e.g., Pathway, Prometheus Group, Dover, NH; Minnova, Empi, St. Paul, MN)	Used for stress, urge, and mixed incontinence in patients who are highly motivated; contraindicated in patients with diminished sensory perception; urinary retention, history of cardiac arrhythmia, cardiac pacemakers, implantable defibrillators, pregnant or attempting pregnancy; vaginal or anal electrodes are contraindicated in moderate or severe pelvic organ prolapse
Extracorporeal magnetic stimulation	Pulsed magnetic stimulation to pelvic floor musculature causing depolarization of motor neurons, thus inducing pelvic floor muscle contraction; stimulation is provided through a specially designed chair that contains a device for producing a pulsing magnetic field (e.g., Neotonus, Inc., Marietta, GA)	Used for treatment of stress, urge, and mixed incontinence; contraindicated in patients with demand cardiac pacemakers or metallic joint replacements; may be useful treatment option when other approaches fail or are not feasible
Antiincontinence devices		
Pessaries	Intravaginal devices designed to support the bladder neck, relieve minor to moderate pelvic organ prolapse, and change pressure transmission to the urethra (e.g., Cooper Surgical (Milex), Trumbull, CT; Mentor Corporation, Santa Barbara, CA)	Used for female stress incontinence and mild to moderate pelvic organ prolapse; in postmenopausal women, topical estrogen therapy is typically prescribed to prevent ulceration and breakdown of vaginal tissue; requires good manual dexterity to manipulate device
Bed or pant alarms	Sensor devices that respond to wetness; used to awaken or alert individuals via noise or vibrating mechanism (e.g., Nite Train-r, Koregon Enterprises, Inc., Beaverton, OR; Wet Call Alarm, AliMed, Dedham, MA)	Primarily used for nocturnal enuresis in children; system available for monitoring incontinence in home care and institutional environments
Urethral compression device (men only)	Penile clamp (e.g., Cunningham Incontinence Clamp, Bard Medical, Covington, GA; ActiCuf, GT Urological, Minneapolis, MN; Cook Continence, Cook Wound/Ostomy/Continence, Spencer, IN)	Used in male stress incontinence patients who are intact and have good manual dexterity
External collection devices (men only)	Condom catheter with leg bag	Used in men with urge, stress, and overflow incontinence and in those with functional impairments
Catheters	Disposable, intermittent urethral catheters and indwelling urethral and suprapubic catheters	Used for overflow incontinence; used in patients who are bed-bound or with significant mobility impairments and severe incontinence; those with terminal illness; those with sacral pressure ulcers until healing occurs

(continued)

TABLE 94-3 Nonpharmacologic Management of Urinary Incontinence (continued)

Intervention	Description	Patient Characteristics
Supportive interventions		
Toileting substitutes and other environmental modifications	Female and male urinals, bedside commodes, elevated toilet seats	Used for patients with mobility impairments that make reaching a toilet in timely fashion difficult
Absorbent products	Variety of reusable and disposable pads and pant systems; some products contain a polymer that absorbs and wicks urine away from the body	Used for all types of incontinence
Physical therapy	Gait and/or strength training	Used for frail elderly patients with mobility impairments that make reaching a toilet in timely fashion difficult

oxybutynin XL administration and, probably less importantly, the lower peak plasma drug concentration are believed to be the reasons for fewer dose- and concentration-dependent adverse effects and better patient tolerance with the XL preparation compared with oxybutynin IR.[61] Elimination of oxybutynin XL is not known to be altered in patients with renal or hepatic impairment or in geriatric patients (up to age 78 years).[58] The absence of an effect of advanced age on oxybutynin XL pharmacokinetics is unexpected because clearance of oxybutynin IR is significantly lower (by approximately 50%) in older patients compared with younger individuals.

Controlled studies have demonstrated that oxybutynin XL is significantly more effective than placebo and is as effective as oxybutynin IR in terms of reducing the mean number of UI episodes, restoring continence, decreasing the number of micturitions per day, and increasing urine volume voided per micturition.[34,35,50–52,62–64]

In short-term studies of up to 12 weeks' duration, oxybutynin XL was better tolerated than oxybutynin IR, with approximately 7% of patients discontinuing treatment because of adverse effects (compared with approximately 27% of those taking oxybutynin IR).[30,35,50,51,57,58] The rate and severity of adverse effects did not differ significantly between elderly persons (≥65 years old) and younger adults using the XL preparation. A 12-week study demonstrated the superiority of oxybutynin XL over tolterodine IR in reducing the mean number of weekly incontinence episodes and micturitions.[43]

In the Overactive Bladder: Performance of Extended-Release Agents (OPERA) trial, oxybutynin XL and tolterodine long-acting (LA) were equally effective in decreasing the mean number of incontinence episodes, but oxybutynin XL was superior in reducing weekly micturition frequency and achieving total dryness.[65]

TABLE 94-4 Pharmacotherapeutic Options in Patients with Urinary Incontinence

Type	Drug Class	Drug Therapy (Usual Dose)	Comments
Overactive bladder	Anticholinergic agents/ antispasmodics	Oxybutynin IR (2.5–5 mg two, three, or four times daily), oxybutynin XL (5–30 mg daily), oxybutynin TDS (3.9 mg/ day) (apply one patch twice weekly), oxybutynin gel (1 sachet [100 mg] topically daily), tolterodine IR (1–2 mg twice daily), tolterodine LA (2–4 mg daily), trospium chloride extended release (60 mg daily), solifenacin (5–10 mg daily), darifenacin (7.5–15 mg daily), fesoterodine (4–8 mg daily)	Anticholinergics are first-line drug therapy (oxybutynin or tolterodine is preferred)
	Tricyclic antidepressants (TCAs)	Imipramine, doxepin, nortriptyline, or desipramine (25–100 mg at bedtime)	TCAs are generally reserved for patients with an additional indication (e.g., depression, neuropathic pain)
	Topical estrogen (only in women with urethritis or vaginitis)	Conjugated estrogen vaginal cream (0.5 g) three times per week for up to 8 months. Repeat course if symptom recurrence, or use estradiol vaginal insert/ring [2 mg (one ring)] and replace after 90 days if needed	Marginally effective for OAB; few adverse effects with vaginal cream and insert
Stress	Duloxetine[a]	40–80 mg/day (one or two doses)	Even though not FDA approved, duloxetine is first-line therapy; most adverse events diminish with time, so support patient during initial period of use
	α-Adrenergic agonists	Pseudoephedrine (15–60 mg three times daily) with food, water, or milk Phenylephrine (10 mg four times daily)	Pseudoephedrine and phenylephrine are alternative first-line therapies for women with no contraindication (notably hypertension); phenylpropanolamine was the preferred agent in the class until its removal from the U.S. market in 2000
	Estrogen	See estrogens (above). Works best if urethritis or vaginitis due to estrogen deficiency is present	Considered a less-effective alternative to α-adrenergic agonists and duloxetine. Combined α-adrenergic agonist and estrogen may be somewhat more effective than α-adrenergic agonist alone in postmenopausal women
	Imipramine	25–100 mg at bedtime	Imipramine is an optional therapy when first-line therapy is inadequate
Overflow (atonic bladder)	Cholinomimetics	Bethanechol (25–50 mg three or four times daily) on an empty stomach	Avoid use if patient has asthma or heart disease. Short-term use only. Never give IV or IM because of life-threatening cardiovascular and severe gastrointestinal reactions

IR, immediate-release; LA, long-acting; TDS, transdermal system; XL, extended-release.

[a]Not FDA-approved for this use. Doses provided are those best supported by clinical trials to date.

TABLE 94-5 Adverse Event Incidence Rates with First-Line Drugs for Bladder Overactivity[a]

Drug	Dry Mouth	Constipation	Dizziness	Vision Disturbance
Oxybutynin IR	85	40	32	20
Oxybutynin XL	35	7	5	2
Oxybutynin TDS	7	3	1	1
Oxybutynin gel	7	2	2	2
Tolterodine	61	13	6	8
Tolterodine LA	23	6	2	1
Trospium chloride IR	20	10	1	1
Trospium chloride XR	11	9	1	1
Solifenacin	11	5	2	4
Darifenacin	20	15	2	2
Fesoterodine	20	15	2	2

IR, immediate-release; LA, long-acting; TDS, transdermal system; XL, extended-release; XR, extended-release.

[a]All values constitute mean data, predominantly using product information from the manufacturers. Due to the absence of information regarding dizziness for oxybutynin IR in the product information, pooled data from references 52 and 69 have been used.

In another study that pooled results of two open-label studies, tolterodine LA was associated with significantly greater patient-perceived improvement in bladder control and fewer withdrawals due to adverse effects than oxybutynin XL. However, the treatments were similar in terms of patients' or physicians' perception of benefit over baseline and proportions of withdrawals due to lack of efficacy. However, the lack of blinding may have introduced patient and observer bias.[66]

Oxybutynin XL, available only in a tablet formulation, is administered once daily, with or without food, and should not be crushed or chewed (see Table 94–4). Like oxybutynin IR, the dosage does not require adjustment in patients of advanced age or in patients with renal or hepatic impairment. However, treatment should be initiated at the smallest recommended dosage in the elderly (5 mg once daily).[36,58] The maximum benefit of oxybutynin XL may not be realized for up to 4 weeks after starting therapy or after dose escalation. No known clinically relevant drug–drug interactions with either oxybutynin XL or oxybutynin IR have been identified. However, other drugs with anticholinergic activity may increase overall anticholinergic effects (i.e., produce an additive or synergistic pharmacodynamic interaction), as might be expected.[58] Another potential pharmacodynamic interaction involves the mutual antagonism of anticholinergic agents and cholinergic stimulants, such as the acetylcholinesterase inhibitors used to treat dementia.

Extended-Release Transdermal Oxybutynin The oxybutynin transdermal system (TDS), which delivers 3.9 mg/day, is applied twice weekly (every 3 or 4 days). Transdermal absorption of oxybutynin from this formulation bypasses first-pass hepatic and gut metabolism, resulting in similar plasma oxybutynin but lower plasma DEO concentrations compared with levels achieved after administration of an equivalent dose via the oral route.[55,67,68] No dosage adjustment of the TDS product for advancing age is necessary.[48]

Oxybutynin TDS is superior to placebo in reducing the number of incontinence episodes and micturitions and increasing the volume voided per micturition.[47,48] It is similar to oxybutynin IR in reducing the frequency of UUI episodes and improving patient-perceived urinary leakage.[69] Oxybutynin TDS and tolterodine LA are significantly superior to placebo and similar to each other in reducing the frequency of UUI episodes, increasing the volume voided per micturition, attaining complete continence, and improving quality of life.[47]

A combined analysis of two phase III studies demonstrated a significant decrease in the number of UUI episodes and urinary frequency and increase in the volume voided per micturition from baseline with oxybutynin TDS in a study population, half of whom were elderly. These results were similar to those achieved in other studies with younger adults.[70] A subgroup analysis of combined placebo-controlled and open-label studies found similar reductions in numbers of UUI episodes and daily micturitions in patients 65 years and older compared with younger adults.[71]

The most common adverse effects with the TDS formulation are pruritus (15%) and erythema (9%) at the application site. Dry mouth (7%), constipation (3%), dizziness (1%), and abnormal vision (1%) occur less frequently with the TDS formulation than with the IR formulation and with similar frequency compared with oxybutynin XL and tolterodine IR/LA.[43,48]

In a study population in which approximately half were elders, the incidences of total adverse events, dry mouth, constipation, abnormal vision, dizziness, and somnolence with oxybutynin TDS were similar to those observed in younger adults.[70] A subgroup analysis of combined placebo-controlled and open-label studies showed that the incidence of adverse events with oxybutynin TDS in patients 65 years and older was similar to that in younger adults. The rates of pruritus and overall treatment discontinuation were lower in elders compared with younger adults.[71]

Oxybutynin Gel. Oxybutyin, in a topical gel formulation applied once daily, delivers approximately 4 mg/day to the systemic circulation. It has the same indications as other oxybutynin products.[72] Transdermal absorption from this formulation has the same effects on oxybutynin and *N*-desethyloxybutynin plasma concentrations as seen with the TDS patch formulation.[73] No dosage adjustment is necessary for advanced age.[72] There is no clinical experience with the gel formulation in patients with renal or hepatic impairment but no dosage adjustment appears necessary in either pathophysiologic state.[72] Application of sunscreen 0.5 hours before or after application of the gel or showering 1 hour after application of the gel does not affect oxybutynin bioavailability.[72] In a phase III, 12-week, randomized, placebo-controlled study, recipients of the gel formulation (n = 389) exhibited significant reductions in urinary frequency and urge incontinence episodes and an increase in volume voided per micturition compared with placebo recipients (n = 400).[74] There are no data available comparing the gel formulation with an active control. The most common adverse events include pruritus (15%), erythema (9%), dermatitis (1.8%), and site reactions (5.4%) at the application site; xerostomia (7.5%); dizziness (1.5%); headache (1.5%); constipation (1.3%); and pruritus (1.3%).[72]

Immediate-Release Tolterodine Tolterodine is a competitive muscarinic receptor antagonist that can be considered first-line therapy for UI in patients with symptoms of urinary frequency, urgency, or urge incontinence.[37]

Controlled studies demonstrated that tolterodine was significantly more effective than placebo and as effective as oxybutynin IR in decreasing the mean daily number of micturitions and increasing the mean volume voided per micturition.[31,38–42,75,76] Although three controlled trials showed a significant decrease in the mean number of incontinence episodes per 24 hours compared with placebo, most other studies have not confirmed the finding, and the manufacturer's package insert does not claim a significant improvement in this parameter.[32,38–42,76] The only controlled study of the ability of tolterodine to restore urinary continence reported an insignificant effect size of 9% over placebo.[38]

Extended-Release Tolterodine In a controlled study of 1,529 adult outpatients with urinary frequency and UUI, tolterodine LA, an extended-release formulation of tolterodine, significantly

decreased the mean number of weekly incontinence episodes (23% effect size over placebo and 7% effect size over tolterodine IR). Premature study withdrawal rates did not differ significantly between the two active treatments, but dry mouth was observed significantly less often in patients taking the LA formulation than among those receiving the IR formulation.[44]

Tolterodine LA was significantly superior to placebo and similar in elderly and young patient populations in reducing the frequencies of incontinence episodes and micturitions, increasing the volume voided per micturition and ability to complete tasks before voiding, and enhancing patient perception of benefit. Adverse effect types and frequencies were similar in the two age groups.[77]

A major consideration in using tolterodine is its pharmacokinetics, specifically its metabolism. The agent is predominantly eliminated by hepatic metabolism, which is partially under the control of genetic polymorphism.[37] The principal metabolic pathway in extensive metabolizers involves oxidation of the parent drug by CYP isoenzyme 2D6 to the active 5-hydroxymethyl metabolite (DD01), followed by further oxidation and dealkylation. In poor metabolizers who lack the CYP 2D6 (approximately 7% of the U.S. population), the principal metabolic pathway involves CYP 3A4, with dealkylation of the amino group, oxidation to a dealkylated hydroxy metabolite, and further oxidation to a dealkylated acid metabolite that undergoes glucuronidation. Because tolterodine is principally metabolized by CYP 3A4 in this case, its elimination may be impaired by inhibitors of this isoenzyme (e.g., fluoxetine, sertraline, fluvoxamine, macrolide antibiotics, azole antifungals, and grapefruit juice). For example, fluoxetine, an inhibitor of CYP 2D6 and 3A4, decreases the metabolism of tolterodine to DD01. The result is a mean 4.8-fold increase in the tolterodine area under the plasma concentration–time curve (AUC), mean 52% decrease in peak plasma concentration, and mean 20% decrease in the AUC of DD01.[37] Whether tolterodine significantly alters the pharmacokinetics of drugs metabolized by CYP 2D6 is unknown, so caution is advised with concurrent use with agents metabolized by CYP 2D6.

Single-dose interaction studies have demonstrated that concurrent administration of tolterodine LA with antacid leads to rapid release of drug (70% within 4 hours) and a mean 1.5-fold elevation in tolterodine peak plasma concentration compared with placebo. The same studies showed that the pharmacokinetics of oxybutynin XL were unaltered by concurrent antacid administration.[78] Another single-dose study showed that concurrent administration of tolterodine LA with omeprazole 20 mg once daily resulted in significantly increased peak plasma tolterodine concentrations compared with tolterodine LA given without prior omeprazole use. Conversely, no significant differences in peak plasma concentration of oxybutynin were evident when the XL formulation was administered with or without omeprazole. However, the AUCs of both agents were not significantly affected by omeprazole administration.[79] The clinical implication of this interaction is unclear. Whether a similar interaction exists with histamine H_2-receptor antagonists is unknown.

One of two phase I pharmacokinetic studies comparing tolterodine pharmacokinetics in healthy elderly volunteers (age 64–80 years) with those in healthy volunteers younger than 40 years found no significant differences in pharmacokinetic parameters between the groups. However, in the second phase I study, the mean serum concentrations of tolterodine and DD01 were 20% and 50% greater in elderly volunteers than in young healthy volunteers, respectively. Despite possibly altered pharmacokinetics in elderly individuals, no differences in the incidences and severity of adverse events between these age groups have been noted in clinical trials, so no dosage adjustment is recommended on the basis of age alone.[37]

Tolterodine elimination is diminished in patients with impaired hepatic function. Patients with hepatic cirrhosis who are extensive metabolizers exhibit a significantly higher mean AUC of DD01, higher serum tolterodine and DD01 concentrations, and longer terminal disposition half-life of tolterodine and DD01 than do healthy subjects who are extensive metabolizers. The tolterodine AUC is higher in cirrhotic patients who are poor metabolizers than in healthy people who are poor metabolizers.[37] If use of tolterodine cannot be avoided in patients with hepatic impairment or in those receiving inhibitors of CYP 3A4 (and possibly inhibitors of CYP 2D6), the initial dose should be reduced by 50% to tolterodine IR 1 mg twice daily or tolterodine LA 2 mg once daily.[37] No formal tolterodine dosage recommendation is possible based on available information for individuals who concurrently have hepatic impairment and are taking a CYP 3A4 and/or 2D6 inhibitor. Intuitively, the initial dose should not exceed 1 mg twice daily (IR) or 2 mg once daily (LA).

Elimination of tolterodine has not been evaluated in patients with impaired renal function; therefore, the drug should be used more cautiously in such individuals (i.e., starting dose of IR product is 1 mg twice daily with gradual dose escalation, if needed, to the usual maximum of 2 mg twice daily or a starting dose of the LA formulation is 2 mg once daily with gradual dose escalation, if needed, to the usual maximum of 4 mg once daily).[37]

Tolterodine is better tolerated than oxybutynin IR, with approximately 8% of patients discontinuing treatment prematurely (compared with approximately 27% of individuals taking oxybutynin IR).[30,32,38,39,41,50,79] The most common adverse effects of tolterodine are dry mouth, dyspepsia, headache, constipation, and dry eyes.[37]

Tolterodine, available only as a tablet formulation, can be taken with or without food. The LA product should not be crushed or chewed or taken less than 2 hours before or 4 hours after antacid administration. The maximum benefit from tolterodine may not be realized for up to 8 weeks after starting therapy or dose escalation.

Fesoterodine Fumarate Fesoterodine fumarate is a prodrug that is metabolized to the active metabolite, 5-hydroxymethyl tolterodine, by nonspecific plasma esterases. It is an alternative first-line therapy for UI in patients with symptoms of urinary frequency, urgency, or urge incontinence.[80] While both hepatic metabolism and renal excretion contribute to the elimination of the active metabolite, no dosage adjustment is necessary in patients with mild to moderate renal or hepatic impairment. The usual starting dose is 4 mg daily, increasing to 8 mg daily, as needed and tolerated. The dose of fesoterodine should not exceed 4 mg daily in the presence of severe renal impairment (creatinine clearance <30 mL/min [0.50 mL/s]) or in patients also taking potent CYP3A4 inhibitors. Fesoterodine has not been studied and is not recommended in patients with severe hepatic impairment.[80,81]

Placebo-controlled studies have demonstrated that fesoterodine 4 and 8 mg daily reduces the number of micturitions/day and the frequencies of incontinence episodes and urgency episodes per week, and the drug increases the number of continent days/week and volume voided/micturition. It also improves quality-of-life compared with placebo. Response is dose-related, with greater responses occurring with the 8 mg versus the 4 mg daily dose (exception: micturition frequency). In the only active comparator trial, fesoterodine 4 and 8 mg and tolterodine LA 4 mg (all given once daily) were all significantly superior to placebo in the majority of efficacy parameters. Fesoterodine and tolterodine were not compared statistically in the trial.

In a post hoc comparison, fesoterodine 8 mg daily was superior to tolterodine LA 4 mg daily in several efficacy parameters. Caution is warranted in interpreting the results of post hoc analyses, however.

The most common adverse effects of fesoterodine are dry mouth (27%), constipation (5.1%), dyspepsia (2%), and dry eyes (1.6%).[80] The most common adverse effects in the active comparator trial were dry mouth (3.8%, 21.7%, 16.9%); constipation (3.3%, 4.5%,

2.8%); and dry eyes (2.2%, 4.2%, <1%) in the fesoterodine 4 and 8 mg and tolterodine LA 4 mg recipients, respectively.[80,81]

At this time, fesoterodine does not appear to be a significant advance on existing anticholinergics in managing UUI.

Trospium Chloride Trospium chloride is a quaternary ammonium anticholinergic. It was approved in 2004 by the U.S. Food and Drug Administration (FDA) for the management of overactive bladder but has been available for many years in other countries. Trospium chloride has been comprehensively reviewed.[82] The data discussed here derive from that review, supplemented with detailed clinical trial data.

Preclinical studies have demonstrated that trospium chloride is an antimuscarinic agent in bladder and gastrointestinal tract tissues. It is poorly absorbed after oral administration (<10%), and food reduces bioavailability by 70% to 80%. It is principally cleared by the renal route (70%), with 80% of urinary excretion accounted for by the parent compound. The mean terminal disposition half-life in the presence of normal renal function is 10 to 12 hours. Advancing age and mild to moderate hepatic impairment do not affect trospium chloride pharmacokinetics to a clinically significant degree. In contrast, renal impairment does significantly reduce drug clearance. When creatinine clearance is less than 30 mL/min (0.50 mL/s), AUC is increased by a mean of 4.5-fold, peak plasma concentration by a mean of twofold, and terminal disposition half-life by a mean of two- to threefold.

Eleven published English-language studies on the efficacy/tolerability of trospium chloride for treatment of UUI are available. Except for the two trials (one published) described in the product information, clinical trials have emphasized cystometric, not clinical, endpoints.[83–92]

The paucity of clinical outcome data makes difficult the evaluation of trospium chloride compared with other approved anticholinergics. Although trospium chloride is statistically superior to placebo, the absolute differences in results between trospium chloride and placebo call into question the clinical relevance of such differences. In the four trials with active controls, results with trospium chloride were statistically equivalent to those with oxybutynin IR and tolterodine IR.[88–91] No comparative data with LA formulations of these two agents are available.

In a study involving a large proportion of elders (mean age, 63 years), the decreases in the number of UUI episodes and daily micturitions and increase in volume voided per micturition were significantly greater in trospium chloride recipients compared with placebo recipients.[92]

The expected anticholinergic adverse effects occur with trospium chloride as well. Of interest, the frequency of these events is increased in patients 75 years and older compared with younger subjects. This occurrence is believed to be pharmacodynamic (i.e., increased sensitivity) and not pharmacokinetic in nature. No data at present support the hypothesis that trospium chloride is less neurotoxic than nonquaternary ammonium anticholinergics (based on the hypothesis of reduced transit across the blood–brain barrier of trospium chloride due to its positive electrical charge on the quaternary nitrogen). Available drug–drug interaction data are clearly inadequate.

The usual dosage regimen is 20 mg twice daily. The drug should be taken on an empty stomach. Dosage reduction (by 50% of the daily dose) is recommended when creatinine clearance is less than 30 mL/min (0.50 mL/s). In patients 75 years and older, dose reduction to 20 mg once daily should be considered based upon tolerability. At this time, trospium chloride does not appear to be a significant advance over oxybutynin and tolterodine in managing UUI.

Extended-Release Trospium Chloride Like the immediate-release formulation, extended-release trospium chloride 60 mg daily is an alternative first-line therapy for treatment of overactive bladder with symptoms of UI, urgency, and urinary frequency.[93]

Because food decreases the bioavailability by 35% to 60%, extended-release trospium chloride must be taken on an empty stomach (1 hour before or 2 hours after meals).[93,94] Trospium is eliminated primarily unchanged in the urine. The pharmacokinetics of this version of trospium chloride in patients with mild to moderate renal impairment have not been studied, and it is not recommended in patients with severe renal impairment (creatinine clearance <30 mL/min [0.50 mL/s]).[93]

Extended-release trospium chloride was evaluated in two 12-week, randomized, controlled studies. In a Phase III study, extended-release trospium chloride 60 mg daily (n = 298) improved urinary frequency, urgency, and UI more than placebo did (n = 303).[95] In another phase III study, extended-release trospium chloride 60 mg daily (n = 267) improved the number of voids per day, number of UUI episodes per day, number of days with no UUI episodes, urgency severity, volume voided per micturition, and overactive bladder (OAB) Symptom Composite Score compared with placebo (n = 276).[96] There are no studies comparing extended-release trospium chloride with an active control.

The most common adverse effects with extended-release trospium chloride have been dry mouth (11%), constipation (9%), dizziness (2%), dry eyes (1.6%), flatulence (1.6%), nausea (1.4%), and abdominal pain (1.4%).[93]

At this time, extended-release trospium chloride does not appear to be a significant advance on trospium chloride or other existing anticholinergics in managing UUI.

Solifenacin Succinate Solifenacin succinate was approved by the FDA in late 2004 for treatment of overactive bladder with urge incontinence, urgency, and urinary frequency. Solifenacin succinate has been comprehensively reviewed.[97] The data discussed here derive from that review, supplemented with detailed clinical trial data.

Preclinical studies demonstrated that solifenacin is an antagonist at M_1, M_2, and M_3 muscarinic cholinergic receptors. Based on comparative ex vivo and animal studies with solifenacin and oxybutynin, solifenacin is believed to be a "uroselective" agent. The drug is well absorbed (mean absolute bioavailability, 88%), and food has no clinically relevant effect on absorption.[98,99] It is principally eliminated via metabolism and renal excretion of metabolites, with renal excretion of parent compound less than 10% of the dose. With a mean terminal disposition half-life of 50 to 60 hours, the drug can be dosed once daily.[100] Results of two placebo-controlled and two placebo- and active (tolterodine)-controlled clinical trials in UUI are available. Like oxybutynin and tolterodine, solifenacin significantly reduced the number of incontinence episodes, urge episodes, and micturitions per day and increased the volume voided per micturition in a dose-dependent fashion compared with placebo. In the active-controlled trials, solifenacin was statistically superior to tolterodine. However, neither of these two studies directly compared solifenacin and tolterodine.[101,102] Surprisingly, the effect of tolterodine in these trials was no better than that of placebo. A direct comparative trial of tolterodine ER demonstrated that the effect of solifenacin was significantly greater than that of tolterodine ER in terms of reducing the number of UUI episodes and pad usage and in improving patients' perception of their bladder condition.[103] An analysis of pooled data from two phase III studies showed that solifenacin recipients had significant improvement in five of 10 quality of life domains from baseline compared with placebo recipients.[104]

No comparative efficacy/tolerability data with oxybutynin are available. The effect sizes (solifenacin effect minus placebo effect) in these studies were similar to those noted with oxybutynin.

A retrospective analysis of pooled data from elders (mean age 72 years) in four phase III studies showed that compared with baseline, solifenacin recipients achieved a significantly greater decrease in number of UUI episodes, number of urgency episodes, and number of micturitions per day and a greater increase in the proportion of patients who became totally dry compared with placebo recipients.[105]

The recommended dose of solifenacin is 5 mg once daily. If the drug is well tolerated but the effectiveness is not optimal, the dose can be increased to 10 mg once daily. Little additional benefit is generally achieved with doses exceeding 5 mg daily. Solifenacin can be administered with or without food. For patients with creatinine clearance rates less than 30 mL/min (0.50 mL/s) or with moderate hepatic impairment (Child-Pugh class B), the daily dosage should not exceed 5 mg. If the patient has severe hepatic impairment (Child-Pugh class C), the drug should not be used. If the patient is receiving concurrent therapy with one or more potent CYP 3A4 inhibitors, the daily dose should not exceed 5 mg. In contrast to findings of preclinical studies, solifenacin behaves like a nonselective anticholinergic in humans, causing dry mouth, constipation, blurred vision, and other anticholinergic effects to a similar extent as tolterodine in clinical trials and oxybutynin in pharmacokinetic trials. At this time, solifenacin does not appear to be a significant advance over existing anticholinergics in managing UUI.

Darifenacin The data on darifenacin discussed here derive from a review,[106] supplemented with detailed clinical trial data.

Preclinical studies have demonstrated that darifenacin is an antagonist at M_1, M_3, and M_5 muscarinic cholinergic receptors. As with solifenacin, darifenacin is believed to be "uroselective" on the basis of preclinical data. The mean absolute bioavailabilities of the 7.5-, 15-, and 30-mg extended-release (ER) formulations are 15%, 19%, and 25%, respectively. Bioavailability is affected by formulation, CYP 2D6 genotype, dose, and race. Bioavailability is enhanced using an ER formulation (70%–110% higher than IR), in heterozygous CYP 2D6 extensive metabolizers and poor metabolizers (40%–90% higher than homozygous extensive metabolizers), and white race (56% higher than Japanese). Darifenacin is extensively metabolized, with cumulative urinary excretion of the parent compound less than 10%. The 2D6 and 3A4 isoenzymes of CYP are responsible for darifenacin metabolism. With a mean terminal disposition half-life of 3 to 5 hours (depending on CYP 2D6 metabolizer status), an ER formulation is needed to allow once-daily dosing. Results of four placebo-controlled clinical trials (one published) on UUI are available. Although a comparative study of darifenacin with oxybutynin IR showed that both agents significantly decreased the number of UUI episodes and their severity as well as urinary urgency and the number of micturitions compared with placebo, the active treatments were not directly compared.[107] A comparison with tolterodine IR and placebo showed that darifenacin 15 mg and 30 mg significantly decreased the number of UUI episodes from baseline after 2 weeks compared with placebo, but only the 30-mg daily dose continued to be superior to placebo after 12 weeks. Compared with placebo, tolterodine IR did not significantly decrease the number of UUI episodes from baseline at either time point. Darifenacin 30 mg once daily achieved a significantly greater decrease in the number of UUI episodes compared with tolterodine IR at both time points. At 12 weeks, both darifenacin and tolterodine IR produced significant improvements from baseline in the number of micturitions per day and volume voided per micturition compared with placebo.[108]

A large pooled subanalysis of patients 65 years and older from three phase III studies demonstrated that darifenacin produced a significant decrease in the number of UUI episodes, urgency episodes, and micturition frequency and an increase in volume voided per micturition compared with placebo.[109] No comparative efficacy/tolerability data with anticholinergics other than tolterodine IR and oxybutynin IR are available.

The recommended daily dose of darifenacin is 7.5 to 15 mg once daily of the ER oral formulation. As with solifenacin, darifenacin behaves like a nonselective anticholinergic in humans, causing dry mouth, constipation, and other well-known anticholinergic adverse effects. Dry mouth was significantly more common with oxybutynin IR than either darifenacin or placebo.[110] In one study, the rates of treatment discontinuation and adverse events in elderly recipients of darifenacin were similar to those seen in other studies of darifenacin conducted in younger adults.[109] At this time, darifenacin does not appear to be a significant advance over existing anticholinergics in managing UUI.

CLINICAL CONTROVERSY

Should anticholinergic pharmacotherapy be used to treat UUI in patients with mild cognitive impairment or mild or moderate dementia?

Other Anticholinergics and Antispasmodics Other drugs for treatment of UUI are less effective, are no safer, or have not been adequately studied.[28,111] Thus their use is not recommended. Tricyclic antidepressants are generally no more effective than oxybutynin IR, and they exhibit a high incidence of bothersome and potentially serious adverse effects (e.g., orthostatic hypotension, cardiac conduction abnormalities, dizziness, and confusion). They are also potentially life threatening in overdose. Therefore, their use should be limited to individuals who have one or more additional medical indications for these agents (e.g., depression or neuropathic pain); patients with mixed UI (because of their effect of decreasing bladder contractility and increasing outlet resistance); and possibly those with nocturnal incontinence associated with altered sleep patterns.[28,111–114] Because of the lower incidence of adverse effects, desipramine and nortriptyline may be preferred over imipramine and doxepin. However, due to their lower anticholinergic activity, they may not be as effective.

CLINICAL CONTROVERSY

Which anticholinergic agent should be used as first-line pharmacotherapy of UUI (oxybutynin, tolterodine, trospium chloride, solifenacin, darifenacin, or fesoterodine) and which formulation of oxybutynin (oral IR, oral XL, TDS patch, or topical gel) or tolterodine (oral IR, oral LA) is unclear. Financial considerations currently favor generic oxybutynin IR, and this is the initial choice of many clinicians. Due to differences between agents in terms of adverse event rates, patient comorbidities may favor the use of more expensive branded agents.

Propantheline, a quaternary ammonium anticholinergic and potential treatment, produces a high incidence of adverse effects and is only modestly effective for UUI.[115–119] When used, propantheline appears to be best tolerated at a dose no more than 15 mg three times daily plus 60 mg at bedtime.[115]

Flavoxate is a tertiary amine that relaxes smooth muscle in vitro. Four controlled trials revealed that flavoxate is no more effective than placebo for treatment of UUI; therefore, flavoxate is not recommended.[28]

Dicyclomine hydrochloride, an anticholinergic agent that relaxes smooth muscle, produced minimal benefit as well as bothersome adverse effects in two small studies.[120,121]

Hyoscyamine, an anticholinergic and antispasmodic drug related to atropine, has been suggested for treatment of UUI, but data recommending its use are insufficient.[28]

In a meta-analysis, 50 randomized, controlled trials and three pooled analyses were examined for significant (with P <0.05) and nonsignificant (NS) differences. Adverse events were seen less frequently with use of LA products, as compared with IR formulations (oxybutynin: incidences of any AE, xerostomia, and moderate–severe or severe xerostomia; tolterodine: incidence of xerostomia). Of interest, the incidence of headache was higher with the use of LA versus IR formulations of tolterodine. The efficacy of LA tolterodine compared with the IR formulation favored the LA formulation for the parameters of number of micturitions and volume voided per micturition. However, the number of incontinence episodes and pad use were similar for the two formulations.[122]

For tolterodine IR, efficacy was similar for the 2 mg and 4 mg daily doses, while only xerostomia occurred more frequently with the 4 mg daily dose. With solifenacin, the only efficacy parameter different for the 5 mg and 10 mg daily doses was the percentage of patients with a 50% or greater reduction in incontinence episode frequency (10 mg > 5 mg). The 10 mg daily dose of solifenacin was associated with higher frequencies of study withdrawal due to adverse events, xerostomia, and constipation than was the 5 mg daily dose. For darifenacin, the 15 mg daily dose, as compared with the 7.5 mg daily dose, was associated with higher frequencies of study withdrawal due to adverse events, xerostomia, and constipation. Also, the 30 mg daily dose, as compared with the 15 mg daily dose, was associated with higher frequencies of xerostomia and constipation.[122]

For comparisons between drugs, only for oxybutynin versus tolterodine were the data adequate for meta-analysis. The IR products were similar in efficacy. Oxybutynin IR was associated with higher frequencies of any adverse event, study withdrawal due to adverse events, xerostomia of any grade, and moderate to severe or severe xerostomia, compared with tolterodine IR. Oxybutynin IR was also associated with higher frequencies of xerostomia and severe xerostomia than was tolterodine LA.[122]

Lastly, oral oxybutynin IR/tolterodine LA, as compared with the oxybutynin TDS (patch) formulation, produced similar reductions in the number of incontinence episodes. However, the oral agents were associated with higher frequencies of xerostomia and constipation, compared with the TDS (patch) formulation. In contrast, the TDS (patch) formulation was associated with higher frequencies of local (application site) reactions and study withdrawal due to adverse effects, compared with the oral agents.[122] The analysis predated the availability of the oxybutynin topical gel formulation.

In summary, the following can be concluded on the basis of available data. LA formulations are generally preferable over IR ones in terms of improved tolerability. Dose escalation of IR formulations may result in improved efficacy, albeit limited, at the cost of an increase in adverse event frequency/severity. The TDS (patch) route does not provide significant advantages over the oral route. No conclusion can be made currently with regard to the topical gel route.

Table 94–5 lists the adverse event frequencies for the most common events for oxybutynin, tolterodine, trospium chloride, solifenacin, darifenacin, and fesoterodine based on manufacturers' product information.

Botulinum Toxin A Enthusiasm is considerable for the application of botulinum toxin A for treatment of voiding dysfunction. Botulinum toxin is a naturally occurring powerful muscle relaxant produced by *Clostridium botulinum*.

Injected into smooth or striated muscle, botulinum toxin acts as a neurotoxin by temporarily paralyzing the muscle. The mechanism of action of the paralytic effect is generally ascribed to prevention of the release of the neurotransmitter acetylcholine into the synapse at the neuromuscular junction, although other pathways in neurotransduction may also be affected.

This compound is commercially produced for medical use in a number of conditions such as muscle spasticity, hyperhidrosis, and cosmetic reduction of skin wrinkles. It does not carry an FDA-approved indication in any lower urinary tract disorders, although many studies are ongoing. In the urinary tract, it can be used to treat overactive bladder (detrusor) muscle as well as external urethral sphincter spasticity. Botulinum toxin has been used successfully and safely in patients with neurogenic bladder dysfunction and nonneurogenic detrusor overactivity and overactive bladder.[123–125]

Botulinum toxin is delivered using a cystoscope equipped with a needle. The usual dosage is between 100 and 300 units per session. It is injected through the needle directly into the bladder muscle in 10 to 30 injections spaced over 5 to 10 minutes. The procedure is carried out as an outpatient procedure without general anesthesia. The duration of therapeutic effect varies, lasting usually from 4 to 8 months. Repeat injections are necessary to maintain the beneficial effects.

The adverse effects of botulinum toxin A when used in the urinary tract most frequently include dysuria, hematuria, urinary tract infection, and urinary retention. Urinary retention occurs in up to 20% of treated individuals and persists until the paralytic effects have worn off (up to 6 to 8 months). Therapeutic and adverse effects may not become evident for 3 to 7 days, presumably because this period of time is required for uptake of the toxin following injection.

Results of an open-label trial of intravesical botulinum toxin A in dimethylsulfoxide in 21 women with refractory idiopathic detrusor overactivity demonstrated a significant reduction in the frequency of incontinence episodes without any effect on postvoid residual urine volumes.[126] Much work remains to determine whether the intravesical (i.e., instillation into the bladder) route for botulinum toxin A administration is feasible for the treatment of OAB.

Catheterization Combined with Medications Patients with UUI and an elevated postvoid residual urine volume due to retention may require intermittent self-catheterization along with frequent voiding between catheterizations.

If intermittent catheterization is not possible, surgical placement of a suprapubic catheter may be necessary. Use of a chronic indwelling catheter should be avoided because of the increased occurrence of urinary tract infections and nephrolithiasis.

Regardless of catheterization status, patients may experience symptom relief with oxybutynin (IR, XL, or TDS formulations), tolterodine (IR or LA formulations), trospium chloride, solifenacin, fesoterodine, or darifenacin, as these agents relax the detrusor muscle and enhance bladder storage. Patients with UUI and symptoms of retention may also benefit from an α-adrenergic receptor antagonist that relaxes the internal bladder sphincter (e.g., prazosin, terazosin, doxazosin, tamsulosin, silodosin, and alfuzosin). Although theoretically of benefit, bethanecol, a cholinergic agonist, has not been demonstrated effective in improving bladder emptying in well-done trials. In addition, it causes numerous bothersome (e.g., muscle and abdominal cramping and diarrhea) and potentially life-threatening adverse effects and should not be used in patients with asthma or heart disease.[28]

Urethral Underactivity

5 Urethral underactivity, or SUI, may be aggravated by agents with α-adrenergic receptor blocking activity, including prazosin, terazosin, doxazosin, tamsulosin, alfuzosin, silodosin, methyldopa,

clonidine, guanfacine, guanadrel, and labetalol. The goal of therapy is to improve the urethral closure mechanism by stimulating α-adrenergic receptors in the smooth muscle of the bladder neck and proximal urethra, enhancing the supportive structures underlying the urethral epithelium, or enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex. There is no role for medications in the management of SUI after radical prostatectomy.[127]

Estrogens Local and systemic estrogens have been used extensively for the pharmacologic management of SUI since the 1940s. Estrogens are believed to work via several mechanisms, including enhancement of the proliferation of urethral epithelium, local circulation, and numbers and/or sensitivity of urogenital α-adrenergic receptors.[128] However, a trial has questioned whether estrogens exert a stimulatory effect on vaginal collagen production, at least over the short term.[129]

Open trials support the use of a variety of estrogens in the management of SUI: transdermal estradiol, conjugated estrogen vaginal cream, Estring, oral conjugated estrogen, oral quinestradol, oral estriol, intramuscular estrogens, estriol vaginal suppositories, and oral estradiol.[130] Variable effects of estrogen treatment on urodynamic parameters, such as maximum urethral closure pressure, functional urethral length, and pressure transmission ratio, have been noted in these studies. Progestogens have an antagonistic effect compared with estrogens, by reducing genitourinary tract muscle tone.

Results of four placebo-controlled comparative trials have not been as favorable, finding no significant clinical or urodynamic effects for oral estrogen compared with placebo.[131–134] In fact, observational studies have documented that estrogen use is associated with an increased risk of UI compared with that in nonusers.[135–138] Systemic estrogen therapy is associated with numerous adverse effects, including mastodynia, uterine bleeding, nausea, thromboembolism, cardiac and cerebrovascular ischemic events, and enhancement of the risk of certain cancers.[111] If estrogens are to be used for treatment of SUI, only topical products should be administered. Estrogen use is best justified when SUI exists with urethritis or vaginitis due to estrogen deficiency.

***α*-Adrenergic Receptor Agonists** Numerous open trials have supported the use of a variety of α-adrenergic receptor agonists in SUI, including ephedrine, norfenefrine, phenylpropanolamine, and midodrine.[130] Phenylpropanolamine was withdrawn from the U.S. market in 2000 because of a risk for stroke in women using the agent.[139] Some patients may have leftover supplies of this agent or may obtain it from international sources. If so, individuals with the contraindications listed later in the chapter (especially coronary artery disease and/or cardiac arrhythmias) should be warned against self-treatment with this or other α-adrenergic receptor agonists.

Placebo-controlled comparative trials with phenylpropanolamine, norfenefrine, and norephedrine support the modest efficacy of these agents for treatment of mild or moderate SUI.[130,140] These agents have been found to variably affect maximum urethral closure pressure and functional urethral length.

Adverse effects include hypertension, headache, dry mouth, nausea, insomnia, and restlessness.[111] Contraindications to the use of these agents include the presence of hypertension, tachyarrhythmias, coronary artery disease, myocardial infarction, cor pulmonale, hyperthyroidism, renal failure, and narrow-angle glaucoma.

Usual doses for pseudoephedrine and phenylephrine are listed in Table 94–4.

Several studies have evaluated whether the clinical and urodynamic effects of a combination of estrogen and an α-adrenergic receptor agonist exceed those of the individual therapies in SUI.[141–145] In general, combination therapy has resulted in somewhat superior clinical and urodynamic responses compared with monotherapy, including severity of complaints, amount of urine lost per episode, number of daily voluntary micturitions, number of leakage episodes per day, patient preference, pad use, maximum urethral closure pressure, functional urethral length, and pressure transmission ratio.

Duloxetine Duloxetine, a dual inhibitor of serotonin and norepinephrine reuptake, was approved in 2004 for treatment of depression and painful diabetic neuropathy.[146] Its use for treatment of SUI (for which the drug is approved in many countries but not in the United States) is based on studies in rats and cats demonstrating that central serotoninergic and noradrenergic regions are involved in ascending and descending control of urethral smooth muscle and the external urethral sphincter. These mechanisms facilitate the bladder-to-sympathetic reflex pathway, increasing urethral and external urethral sphincter muscle tone during the storage phase. Data documenting this control mechanism in humans are limited. The mean terminal disposition half-life, clearance, and volume of distribution of duloxetine in healthy volunteers are 10 to 12 hours, 114 to 119 L/h, and 1,787 to 1,943 L, respectively. The drug is extensively metabolized to inactive metabolites (via oxidation at the 4, 5, and/or 6 positions in the naphthyl ring, followed by further oxidation or via methylation) with elimination in the urine as conjugated metabolites. CYP 2D6 and 1A2 are involved in the ring oxidations. This involvement was demonstrated in studies of the interaction of duloxetine with the CYP 2D6 substrate desipramine (wherein desipramine's peak plasma concentration, AUC, and terminal disposition half-life were increased 1.7-, 2.9-, and 1.9-fold, respectively, and clearance fell by 66%) and the CYP 2D6 inhibitor paroxetine (wherein duloxetine's peak plasma concentration, AUC, and terminal disposition half-life increased 1.6-, 1.6-, and 1.3-fold, respectively, and clearance fell by 37%). Fluvoxamine, a CYP 1A2 inhibitor, increased duloxetine's peak plasma concentration, AUC, and terminal disposition half-life by over 5-fold, 2.5-fold, and 3-fold, respectively. Thus clinicians must be careful when prescribing duloxetine concurrently with CYP 2D6 and 1A2 substrates or inhibitors. The effect of advancing age on duloxetine pharmacokinetics is not clinically significant. Moderate hepatic dysfunction (Child-Pugh class B) significantly affects duloxetine disposition, increasing mean AUC and terminal disposition half-life by 5-fold and 3-fold, respectively, and reducing clearance 85% compared with controls. Mild or moderate renal impairment (creatinine clearance 30–80 mL/min [0.50–1.34 mL/s]) does not affect drug disposition. In severe renal impairment (hemodialysis patients), mean peak plasma concentration and AUC are both increased 100%, whereas metabolite concentrations are increased up to 900%.

Results of six large clinical trials with duloxetine in SUI have been published. All were double-blinded, randomized, placebo-controlled, and parallel group in design. Compared with placebo, duloxetine therapy produced significant reductions in incontinence episode frequency and number of micturitions per day, improvement in Incontinence quality of life questionnaire scores and patient self-assessment, and increase in mean micturition interval. Results were independent of baseline UI severity (severity based on incontinent episode frequency). Significant intergroup differences were seen by week 4. However, cure rates were generally not improved by duloxetine. When evaluating the absolute differences between treatments, the actual benefit of duloxetine was generally quite modest.

A randomized, placebo-controlled clinical trial evaluated the effects of duloxetine (80 mg daily), pelvic floor muscle training (PFMT), and the combination of both modalities on incontinent episode frequency, incontinence-related quality of life, pad use, and patient global impression of change. Sham PFMT was used in the placebo group. Results indicated that duloxetine plus PFMT were probably additive in effect and that combination therapy afforded greater improvement than either monotherapy.[147]

Although duloxetine is an encouraging development in the pharmacologic management of SUI, its adverse event profile may make adherence problematic. In the SUI trials, treatment-emergent adverse events occurred in 68% to 93% of duloxetine and 50% to 72% of placebo recipients. Premature study withdrawal rates (due to adverse events) were 12% to 33% for duloxetine and 2% to 8% for placebo. The frequencies of individual events in duloxetine recipients were nausea 9% to 46%, headache 7% to 27%, insomnia 13% to 14%, constipation 4% to 27%, dry mouth 4% to 22%, dizziness 8% to 16%, fatigue 10% to 18%, somnolence 8% to 13%, vomiting 6% to 13%, and diarrhea 4% to 6%. Of interest, the drug may be associated with small increases in blood pressure (like venlafaxine, another dual reuptake inhibitor) and withdrawal symptoms (sleep disturbances). Unfortunately, adherence to long-term therapy is quite poor due to a combination of adverse events and lack of efficacy.[148,149]

Despite these negatives, duloxetine is the first drug approved by a regulatory agency for treating SUI. Based on studies conducted to date, a dosage regimen of 40 to 80 mg/day (in one or two doses) appears reasonable. Initiating therapy with 40 mg daily for 2 weeks and then increasing to 80 mg daily (rather than initiating therapy with 80 mg daily) reduces the risks of nausea, dizziness, and premature drug discontinuation.[150] If the drug is to be stopped, it should be withdrawn slowly, reducing the dose by 50% for 2 weeks before discontinuation, unless the situation is potentially life-threatening.[150]

A double-blind, randomized, placebo-controlled clinical trial has recently demonstrated the benefit of venlafaxine 75 mg once daily for 12 weeks over placebo in terms of incontinence episode frequency, voiding interval, quality of life, and patient global impression of improvement.[151]

Overflow Incontinence

Overflow incontinence secondary to benign or malignant prostatic hyperplasia may be amenable to pharmacotherapy. For management of malignant prostatic disease, see Chapter 139. The pharmacotherapy of BPH is discussed in Chapter 93.

CLINICAL CONTROVERSY

The optimal approach to pharmacotherapy of SUI is unclear. Although not supported by evidence-based medicine, many clinicians initiate a trial of topical estrogen, followed by addition of an α-adrenergic receptor agonist in estrogen nonresponders unless contraindicated. Based on available data, duloxetine is the drug of choice for treatment of SUI, provided it is tolerated.

SURGICAL TREATMENT

Only rarely does surgery play a role in the initial management of UI.[152] In the absence of secondary complications from UI (e.g., skin breakdown or infection), the decision to surgically treat symptomatic UI should be based on the premise that the degree of bother or lifestyle compromise to the patient is great enough to warrant an elective operation, and that nonoperative therapy either is undesired or has been ineffective.

Successful application of surgery depends most on defining the underlying abnormalities responsible for UI (bladder vs urethra, underactivity vs overactivity). Once the underlying factors are determined, other considerations include renal function, sexual function, severity of leakage, history of abdominal or pelvic surgery, presence of concurrent abdominal or pelvic pathology requiring surgical correction, and finally the patient's suitability for, and willingness to accept the risks of, surgery.

When patients with uncomplicated SUI become dissatisfied with the initial management approaches of pelvic floor exercises, medications, and/or behavioral modification,[152] surgical treatment assumes the primary role.

Surgical correction of female SUI (urethral underactivity) is directed toward either (a) repositioning the urethra and/or creating a backboard of support, or otherwise stabilizing the urethra and bladder neck in a well-supported retropubic (intraabdominal) position that is receptive to changes in intraabdominal pressure; or (b) improving the sealing mechanism and/or creating compression or otherwise augmenting the urethral resistance provided by the intrinsic sphincteric unit, with (i.e., sling) or without (i.e., periurethral collagen and other injectables) urethral and bladder neck support. Midurethral synthetic slings have become the most common approach to the treatment of SUI in women in the United States. These can be inserted in outpatient procedures that have shorter convalescence periods and allow faster return to usual activities compared with many of the older procedures.

As noted previously, SUI in men is very rare in the absence of prior pelvic surgery, injury, or neurologic disease. In men, SUI can be treated in a number of ways. Collage or other bulking agents can be injected periurethrally and submucosally into the region of the external urinary sphincter. The goal of these injections is to improve the sealing effect of the poorly functioning sphincter mechanism. The vast majority of periurethral bulking injections in men are performed in a retrograde fashion under direct visualization through a cystoscope. This approach is less effective and far less durable than alternative surgical procedures, although it can be performed in the office setting without the need for general anesthesia. The artificial urinary sphincter is generally considered to be the gold standard for treatment of male SUI. Placement of the manually operated silicone device has been associated with very high long-term success and satisfaction rates.[153] Male slings placed through a perineal incision are a newer alternative to the artificial urinary sphincter. However, long-term efficacy and safety data are lacking.

Most patients with UUI are managed nonsurgically with a combination of behavioral modification, pelvic floor exercises, and pharmacologic therapy. Only rarely is surgery applied to the problem of UUI. Surgery for the treatment of UUI generally consists of implantation of a sacral nerve stimulator (neuromodulation) or augmentation (enlargement) cystoplasty. Posterior tibial nerve stimulation is a new office-based percutaneous treatment for UUI or OAB. Long-term efficacy and safety data are lacking. Additional information and a systematic review of these procedures are available.[154]

Few surgical treatments for bladder underactivity are effective. After an appropriate evaluation for reversible causes is performed, the most effective management of this condition is intermittent self-catheterization performed by the patient or a caregiver three or four times per day. Sacral nerve stimulation (neuromodulation) has shown some efficacy in this patient population, but success rates for detrusor underactivity (nonobstructive urinary retention) are inferior to those seen with urinary frequency and urgency. Proper patient selection for this therapy remains poorly defined. Alternative methods of management that are less satisfactory or more invasive include indwelling urethral or suprapubic catheters and urinary diversion.

Urethral overactivity is most commonly caused by anatomic obstruction. Anatomic obstruction in men is most often caused by benign prostatic enlargement (see Chap. 93).

Rarely, bladder outlet obstruction is caused by a functional obstruction at the level of the bladder neck. Hypertrophy of the smooth muscle fibers at the level of the bladder neck in men and women may result in obstruction to the flow of urine. In patients who do not respond to pharmacologic therapy with α-adrenergic receptor antagonists, endoscopic incision using the cystoscope is highly effective in treating this very uncommon condition.

EVALUATION OF THERAPEUTIC OUTCOMES

6 During long-term management of UI, patient-specific clinical signs and symptoms of most distress ("bother") to the individual must be monitored. A daily diary may be useful in this regard. Some of the short-form instruments used in incontinence research for measuring symptom impact and condition-specific quality of life can be used in clinical monitoring. In addition, quantitating the use of ancillary supplies, such as pads, may be useful. The goal of therapy is to minimize the signs and symptoms most bothersome to the patient, as well as the use of pads and other ancillary supplies or devices. Total elimination of UI signs and symptoms may not be possible, and patients and practitioners need to mutually establish realistic goals of therapy. Because the therapies for UI frequently have nuisance adverse effects (e.g., anticholinergic effects such as xerostomia, xerophthalmia, and constipation) that may compromise regimen adherence, the presence and severity of adverse effects must be carefully elicited at each visit to the healthcare practitioner. Emergence of adverse effects may necessitate drug dosage adjustment or use of alternative strategies (e.g., chewing sugarless gum, sucking on hard sugarless candy, or use of saliva substitutes in xerostomia) or even drug discontinuation.

ABBREVIATIONS

AUC: area under the plasma or serum concentration-versus-time curve

BPH: benign prostatic hyperplasia

CYP: cytochrome P450

DD01: 5-hydroxymethyl metabolite of tolterodine

DEO: *N*-desethyloxybutynin

ER: extended release

IR: immediate release

LA: long acting

NS: nonsignificant

OAB: overactive bladder

PFMT: pelvic floor muscle training

SUI: stress urinary incontinence

TDS: transdermal system

UI: urinary incontinence

UUI: urge urinary incontinence

XL: extended release

SECTION 11
IMMUNOLOGIC DISORDERS

CHAPTER 95

Function and Evaluation of the Immune System

PHILIP D. HALL, NICOLE WEIMERT PILCH, AND DANIEL H. ATCHLEY

KEY CONCEPTS

1. Cells of the immune system are derived from the pluripotent stem cell. Hematopoiesis is a closely regulated to assure adequate amounts of each of the different types of blood cells. The development of the different kinds of cells or cell lineages depends on cell-to-cell interactions and hematopoietic growth factors.
2. After activation, dendritic cells express higher concentrations of major histocompatibility complex class II molecules, B7-1, B7-2, CD40, ICAM-1, and LFA-3 molecules than other antigen-presenting cells. They also produce more IL-12. These differences may explain why in vitro dendritic cells are the most efficient antigen-presenting cell.
3. A T lymphocyte expresses hundreds of T-cell receptors (TCRs). All the TCRs expressed on the surface of an individual T lymphocyte have the same antigen specificity.
4. A B lymphocyte can simultaneously express membrane immunoglobulin as IgM (monomeric) or IgD with the same variable region (i.e., antigen-binding site). The B lymphocyte then can secrete different isotypes (e.g., IgM [pentamer], IgA, IgG, IgE) with the same variable region as the membrane immunoglobulin.
5. A serum protein electrophoresis determines the total concentration of circulating immunoglobulins (i.e., IgG, IgA, IgM, IgD, and IgE). If one wishes to determine the concentration of the individual isotypes, one needs to order isotype quantification. The vast majority of clinical laboratories quantitate only IgG, IgM, and IgA because they are the most prevalent isotypes in the bloodstream. In patients with allergic disorders, quantification of IgE may be useful. Depending on the clinical laboratory, results may come back in IU/mL, kIU/L, or mg/L for IgE.
6. An understanding of the mechanism by which immunomodulators act along with an understanding of the immune system allows a clinician to anticipate potential adverse effects. The benefit of manipulating the immune responses must be balanced with the potential consequences and long-term sequela of such manipulation.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The immune system is a complex network of barriers, organs, cellular elements, and molecules that interact to defend the body against invading pathogens. Actually, the *immune system* is composed of two distinct systems of immunity: innate immunity and adaptive immunity. In brief, innate immunity includes a series of nonspecific barriers (physical and chemical), along with cellular and molecular elements strategically predeployed and prepositioned to prevent and/or quickly neutralize infection. Working in concert with innate immunity is adaptive immunity. In contrast to innate immunity, adaptive immunity constantly evolves and adapts against invading pathogens. Its hallmarks include *diversity*, *memory*, *mobility*, *self vs non-self discrimination*, *redundancy*, *replication*, and *specificity*.[1] *Diversity* indicates the capability of the immune system to respond to many different pathogens or strains of pathogens. Immunological *memory* ensures a quicker and more vigorous response to a subsequent encounter with the same pathogen. *Mobility* of components of the immune system enables local reactions to provide systemic protection. *Discrimination of self vs non-self* helps prevent friendly-fire damage of the host by the immune system. *Redundancy* refers to the immune system's ability to produce components with similar biological effects from multiple cells lines, such as inflammatory cytokines. *Replication* of the cellular components of the immune system amplifies the immune response. *Specificity* describes the ability of the immune system to distinguish between dissimilar antigens.

MAJOR TISSUES AND ORGANS OF THE IMMUNE SYSTEM

While numerous cells of the immune system have the ability to migrate to most body tissues, some tissues and organs serve as key members of the immune system. These include primary and secondary lymphoid tissues and organs. *Primary lymphoid tissues*

and organs provide an environment appropriate for the development and maturation of select cells of the immune system. It is here that these select cells of the immune system mature and become tolerant of self and competent to respond to foreign antigens. *Secondary lymphoid organs* provide an environment where various cells of the immune system interact with and respond to trapped foreign antigens.[2]

BONE MARROW

1 Bone marrow is the predominant primary lymphoid tissue of the body because it is the source of all cellular elements of the blood (erythrocytes, leukocytes, and thrombocytes [i.e., platelets]). The few exceptions to this rule are mostly confined to fetal development when some blood cells are transiently produced in the yolk sac, liver, spleen, thymus, and lymph nodes.[3] Regardless of where they are formed, all blood cells arise from common self-renewing pluripotent stem cells via the process of *hematopoiesis* (Fig. 95–1). During hematopoiesis, pluripotent stem cells differentiate along particular myeloid and lymphoid lineages to produce the leukocytes of the immune system, erythrocytes, and thrombocytes.[4,5] Hematopoiesis is controlled by soluble mediators called hematopoietic growth factors/cytokines or colony stimulating factors (CSFs) that are multifunctional and drive responses such as growth, survival, proliferation, differentiation, maturation, and functional activation.[6] The destiny of the leukocytes (if they survive the maturation process) is to become mature cells of the immune system directly from the bone marrow (all leukocytes except T lymphocytes), or to migrate out of the bone marrow to continue their maturation elsewhere (T lymphocytes). Selected hematopoietic growth factors are identified in Figure 95–1, and a more comprehensive list appears in Table 95–1. Currently, four human hematopoietic cytokines have one or more recombinant products that are FDA-approved for clinical use: erythropoietin (EPO); granulocyte colony-stimulating factor (G-CSF); granulocyte-macrophage colony-stimulating factor (GM-CSF); and interleukin 11 (IL-11).[7]

THYMUS

The thymus is a bi-lobed primary lymphoid organ located in the superior mediastinum between the aorta and the sternum. Its primary function is to produce mature T cells (thymus-dependent

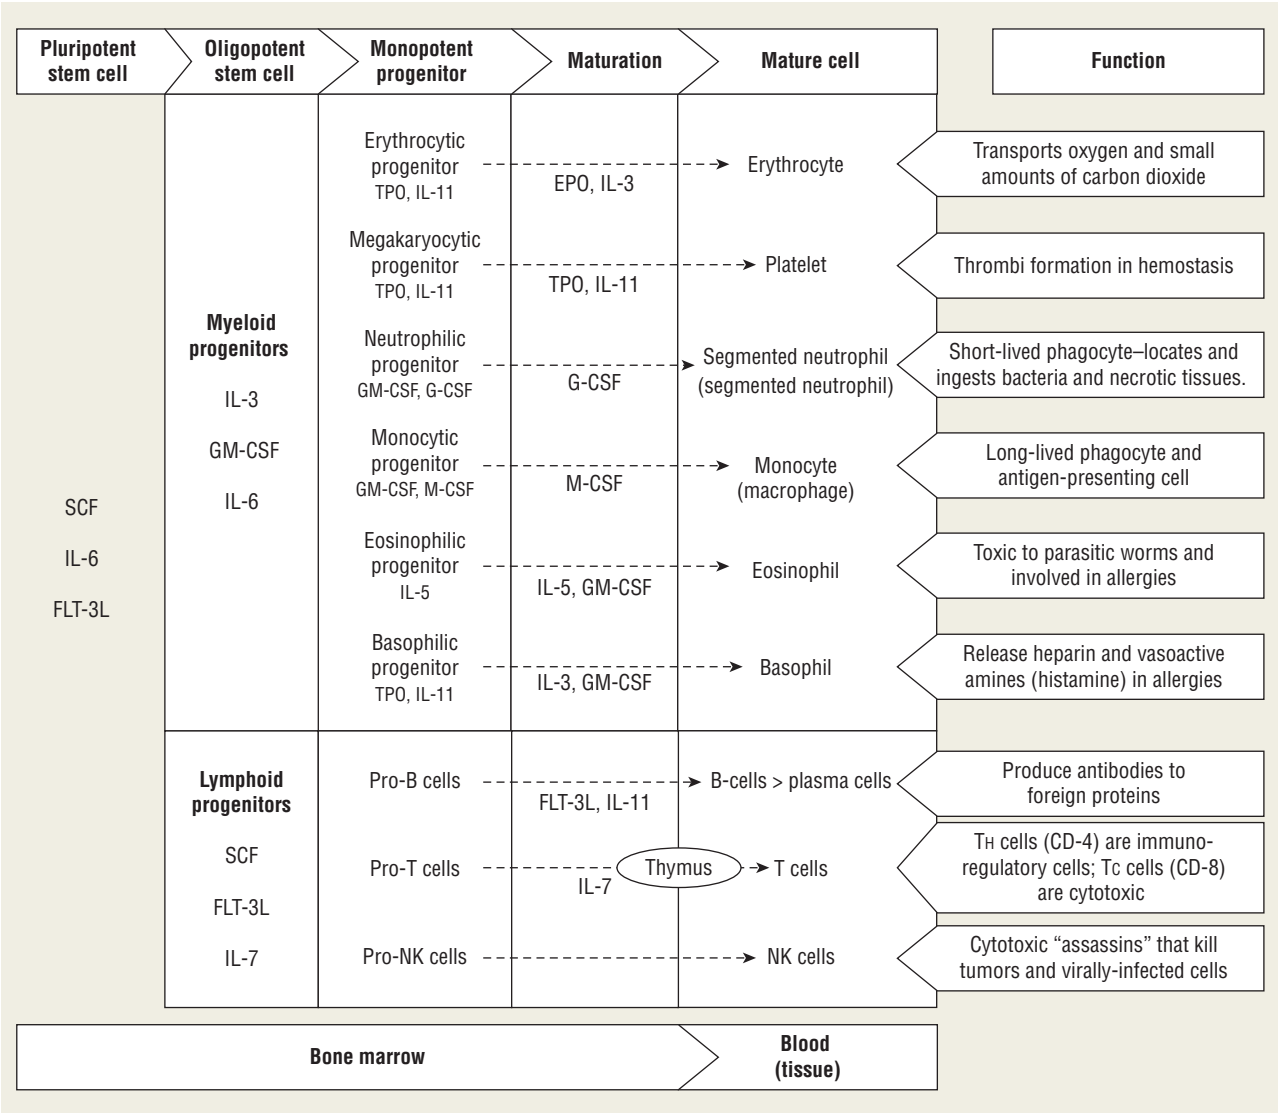

FIGURE 95-1. Basic model of hematopoiesis, outlining the various pathways blood cells take from their origin as bone marrow stem cells through stages in which they are progressively selected to become monopotent mature cells with specific functions. Selected hematopoietic growth factors include: EPO, erythropoietin; FTL-3L, fms-like tyrosine kinase ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; SCF, stem cell factor; TPO, thrombopoietin.

TABLE 95-1 Hematopoietic Growth Factors or Colony Stimulating Factors

Cytokine	Sources	Principal Effects
EPO	Kidney, liver	Erythrocyte production and maturation
GM-CSF	T lymphocytes, macrophages, bone marrow stromal cells	Maturation and activation of granulocytes, monocytes/macrophages, and eosinophils
G-CSF	Macrophages, bone marrow stromal cells	Maturation and activation of neutrophils
M-CSF	Macrophages, bone marrow stromal cells	Maturation and activation of monocytes/macrophages
TPO	Liver, kidney	Platelet production
SCF	Bone marrow stromal cells, constitutively	Stem cell and progenitor cells activation
FLT-3L	Bone marrow stromal cells	Early-acting growth factor
IL-3	T lymphocytes, macrophages,	Maturation and differentiation of hematopoietic and mast cells
IL-5	Activated T lymphocytes	Eosinophil production
IL-6	Activated T lymphocytes, bone marrow stromal cells	Progenitor cell stimulation
IL-7	Bone marrow stromal cells	T-cell maturation/survival
IL-11	Bone marrow stromal cells	Growth factor for B lymphocytes and megakaryocytes

EPO, erythropoietin; FLT-3L, fms-like tyrosine kinase ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; IL. interleukin; M-CSF, macrophage colony-stimulating factor; SCF, stem cell factor; TPO, thrombopoietin.

lymphocytes), which are the leukocytes responsible for cell-mediated immunity, including cytotoxic actions and immunoregulation. Through an intricate multistep process called thymic education, T cells that respond appropriately and are beneficial to the immune system mature and leave the thymus. T cells that fail the thymic education test (99%) are eliminated via apoptosis.[1]

SPLEEN

The spleen is a slender elongated secondary lymphoid organ located in the upper left quadrant of the abdomen that receives blood from the splenic artery. Although it is not a vital organ, it functions as an immunological filter of the blood and destroys defective and old erythrocytes. It contains compartments designated as red pulp and white pulp and provides an environment for the interaction of its filtered debris from blood with antigen-presenting cells and lymphocytes responsible for cell-mediated responses (T cells) and lymphocytes responsible for antibody production (B cells). Red pulp serves as a site of red blood cell degradation, and the white pulp provides an environment for the interaction of B cells and T cells. The spleen sequesters many cellular elements (leukocytes, erythrocytes, and platelets) and can become dangerously congested in a condition termed *splenomegaly*.

LYMPH NODES

Lymph nodes are normally small BB-sized lymphoid organs widely distributed between the groin and the neck. While the spleen filters blood, lymph nodes act as immunological filters for interstitial lymphatic fluid from the body's tissues. Lymph nodes provide an environment for the interaction of filtered debris with antigen-presenting cells and other immune cells (T cells and B cells).[2] Lymph nodes may sequester activated immune cells (or tumor cells) and become inflamed and engorged causing lymphadenopathy.

TABLE 95-2 Functional Divisions of the Immune System

	Innate	Adaptive
Exterior defenses	Skin, mucus, cilia, normal flora, saliva, low pH of the stomach, skin, genitourinary tract	None
Specificity	Limited and fixed	Extensive
Memory	None	Yes
Time to response	Hours	Days
Soluble factors	Lysozymes, complement, C-reactive protein, interferons, mannose-binding lectin, antimicrobial peptides[a]	Antibodies, cytokines
Cells	Neutrophils, monocytes, macrophages, natural killer cells, eosinophils	B lymphocytes, T lymphocytes

[a] Cathelicidins α-defensins, β-defensins.

MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT)

Mucosa-associated lymphoid tissue (MALT) is the most extensive component of human lymphoid tissue and is distributed along mucosal linings of the body.[8] MALT may consist of well-defined networks of primary lymphoid follicles and other associated immunocompetent cells (adenoids, appendix, intestinal Payer's patches, and tonsils), small solitary lymph nodes, or loosely organized clusters of lymphoid cells that are found in intestinal villi. The primary function of these tissues is to filter, trap, and remove pathogens that breach mucosal surfaces. In addition to neutralizing pathogens, MALT generates plasma cells (activated B cells) that secrete IgA antibodies.

As mentioned earlier, the immune system includes two functional divisions: (1) the *innate* or nonspecific which encodes evolutionary genes aimed at providing rapid responses against nonmammalian targets and (2) the *adaptive* or specific which utilizes cells which can genetically rearrange their DNA to create specific structures which bind individual antigens or proteins (Table 95–2).[9] Despite this simple separation, these divisions extensively interact.[10] Awareness of each component of the immune system and the consequences of disrupting homeostasis must be understood in order to appropriately dose, administer, and monitor the effect of medications given to manipulate immune responses.

METHODS TO DISTINGUISH SELF FROM NON-SELF

The immune system is designed to attack and destroy a broad spectrum of foreign antigens/pathogens. The immune system must however be able to distinguish self from non-self, termed *self-tolerance*, in order to avoid unleashing its components onto self-tissues.[11] The body employs many tactics to avoid attacking itself, and when self-tolerance fails this may lead to the development of an autoimmune disease.

INNATE IMMUNE SYSTEM

Physical Defense

Physical and chemical defenses are the most rudimentary form of innate immunity and the first line of defense against invading pathogens. The skin, the largest organ of the body, has the primary role of providing a physical defense. Alterations in the skin, such as burns or abrasions, allow an easy portal of entry for pathogens. The gastrointestinal tract also provides physical defense. The low pH of the stomach (pH 1–2) is inhospitable to most organisms. The rapid

turnover of intestinal cells also limits systemic infection as cells including infected cells are sloughed frequently. Drugs, such as cell-cycle, phase-specific antineoplastics that disrupt the sloughing process, leave the patient at an increased risk for infections. Likewise, the respiratory tract has its forms of physical defense. The mucus coating the epithelial cells serves in part to prevent microorganisms from adhering to cell surfaces, and the cilia lining the epithelium of the lungs help to repel inhaled organisms. The combination of cilia, mucus, and reactive coughing provides a natural barrier to invasion via the respiratory tract. Other examples of mechanical or nonspecific defenses include normal urine flow, lysozymes in tears and saliva, and the normal flora in the throat, the lower gastrointestinal tract, and the genitourinary tract. Disruption of the normal physical defense system through mechanical ventilation, for example, places the host at substantial risk for penetration by a pathogenic organism.[12]

Innate Immune Response

If an infectious pathogen invades and is able to infiltrate through a host's physical defense system, innate immunity is employed to halt progression of the infection. Innate immunity is present from birth and utilizes a preexisting but limited repertoire of receptors to recognize and destroy pathogens. Innate immune cells include subgroups of leukocytes; specifically, monocytes/macrophages, neutrophils, basophils, mast cells and eosinophils. When stimulated by a foreign pathogen, mast cells and basophils secrete inflammatory mediators. Monocytes/macrophages, neutrophils, mast cells, and eosinophils act as phagocytes, which allow them to recognize, internalize, and destroy invading pathogens. This process may occur in two ways: opsonin-dependent or opsonin-independent phagocytosis. For opsonin-dependent phagocytosis, antibody (e.g., IgG), complement (e.g., C3b), or lectin (e.g., C-reactive protein) coat, or opsonize, the infectious pathogens. Once the pathogen is opsonized, the antibody, complement, or lectin binds to the receptors on the phagocyte (Fig. 95–2) and activates the phagocytic process. For opsonin-independent phagocytosis, innate leukocytes utilize pattern recognition receptors. Pattern recognition receptors recognize highly conserved

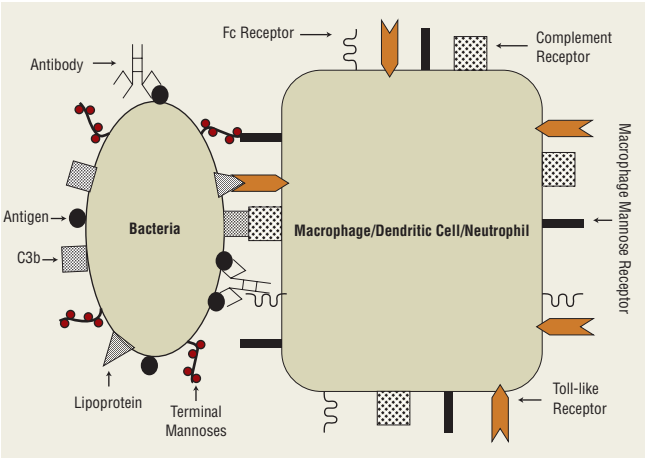

FIGURE 95-2. Phagocytosis of bacteria by macrophages, dendritic cells, and neutrophils. Macrophages, dendritic cells, and neutrophils recognize bacteria opsonized (coated) with antibody or complement (C3b). On the surface of macrophages, dendritic cells, and neutrophils reside receptors for antibody (Fc receptors) and complement (CR1, CR3, CR4). In addition, these cells may recognize the bacteria by pattern recognition receptors on the surface of macrophages, dendritic cells, and neutrophils. Pattern recognition receptors include toll-like receptors, scavenger receptors, and mannose receptors.

TABLE 95-3 Ligands for Pattern Recognition Receptors

Pathogen Ligand	Type of Organism
Lipoteichoic acid	Gram-positive organisms
Lipopolysaccharide	Gram-negative organisms
Mannose	Fungi, gram-positive, gram-negative
Double-stranded RNA	RNA viruses
Triacyl lipopeptides	Gram-positive, gram-negative
Peptidoglycans	Gram-positive
Bacterial flagella	Various

structures present on a large number of microorganisms. These highly conserved structures are essential for the microorganism's survival or pathogenicity. The pattern recognition receptors include the macrophage mannose receptor, macrophage scavenger receptor, and members of the toll-like receptor family. Pattern recognition receptors on the phagocytes directly recognize ligands (Table 95–3) on the surfaces of infectious pathogens leading to immediate phagocytosis of the pathogen (Fig. 95–2). Toll-like receptors are a family of pattern recognition receptors on the cell-surface of innate leukocytes. To date, 11 toll-like receptors have been identified in humans. They recognize a broad spectrum of antigens ranging from lipopolysaccharide and flagellin on bacteria to zymosan on yeast to double-stranded RNA from RNA viruses (Table 95–3). Binding of the ligand to the toll-like receptors allows the phagocyte to recognize and engulf the pathogen. This binding of toll-like receptors to its ligand also results in the secretion of chemokines, inflammatory cytokines, and antimicrobial peptides as well as the increased expression of co-stimulatory proteins (e.g., B7) and the major histocompatibility complex proteins by the phagocyte. This leads to the recruitment and activation of antigen-specific lymphocytes.[10,13,14] Other pattern recognition receptors that mediate phagocytosis include MARCO (macrophage receptor with collagenous structure), DC-SIGN (***D***endritic ***C***ell-***S***pecific ***I***ntercellular adhesion molecule-3-***G***rabbing ***N***on-integrin), and dectin 1.

Cells of the Innate Immune System

Neutrophils, eosinophils, and basophils are considered granulocytes because of the presence of numerous cytoplasm granules in these cells that contain inflammatory mediators or digestive enzymes. Their names are derived from their staining characteristics; neutrophils are named because they stain a neutral pink. Neutrophils comprise the majority of leukocytes in the bloodstream. They are polymorphonuclear cells, often denoted as PMNs for this reason, which serve as the primary human defense against invasive bacteria. Neutrophils migrate from the bloodstream into infected or inflamed tissue in response to chemotactic factors, such as IL-8 and C3a and C5a, breakdown products of complement. In this migration, a process termed chemotaxis, neutrophils reach the site of inflammation and then recognize, adhere to, and phagocytose pathogens. Via the complement and antibody receptors located on its surface, neutrophils can recognize and engulf pathogens opsonized with complement or IgG (antibody). During phagocytosis, the engulfed pathogen is internalized within the phagocyte into a cytoplasmic lysosome. The neutrophil then releases its granular contents into lysosome and generates the release of oxidative metabolites that destroy the engulfed pathogens.[15] Neutrophils can also recognize pathogens via toll-like receptors.

Eosinophils are also granulocytic cells involved in innate immunity. They exhibit motility and migrate from the blood into the tissues. They play a less significant role in combating bacterial infections, but eosinophils play a major role against nonphagocytable multicellular

pathogens, such as parasites. After activation via high-affinity receptor for IgE (i.e., Fcε), eosinophils exocytose their granules causing the release of basic proteins or reactive oxygen species into the microenvironment, causing lysis of the parasite. In addition to Fcε receptors, eosinophils express lower levels of complement receptor 3 and Fcγ for IgG than neutrophils. The high affinity of eosinophils for IgE contribute to their role in the pathogenesis of allergic disorders (i.e., allergic asthma).[16]

Macrophages and monocytes are mononuclear cells capable of phagocytosis. Tissue macrophages arise from the migration of monocytes from the bloodstream into the tissues. Macrophages differ from monocytes by possessing an increased number of Fc and complement receptors. Macrophages are found within specific tissues such as the liver, spleen, gastrointestinal tract, lymph nodes, brain, and others. These specific types of macrophages are often called histiocytes, or referred to by a specialized name depending on the site where they are found (for example, Kupffer cells in the liver, osteoclasts in the bone, microglial cells in the central nervous system). The term reticuloendothelial system (RES) was commonly used to refer to macrophages found in reticular connective tissue, but the preferred nomenclature is now the mononuclear phagocyte system.[17]

Despite the first description in 1868 of Langerhans cells, a type of dendritic cell found in the skin, our current understanding of the biologic function of dendritic cells did not develop until the past decade. Before pathogen recognition, most dendritic cells are in an immature/resting state with limited ability to activate T lymphocytes, but they express numerous receptors (e.g., Fc receptors of IgG and IgE, macrophage mannose receptor, toll-like receptors) enabling rapid antigen recognition. Following antigen recognition and particle engulfment, dendritic cells become activated. This leads to a dramatic increase in their expression of the major histocompatibility complex (MHC) class II, B7, CD40, and adhesion molecules. Dendritic cells then begin to migrate through the tissues towards lymphoid organs (e.g., spleen, lymph nodes) to present antigen to T lymphocytes, causing activation of the adaptive immune system.[18]

❷ In addition to phagocytosing pathogens, macrophages and dendritic cells act as antigen-presenting cells (APCs) to stimulate the adaptive (specific) system. Macrophages and dendritic cells internalize the organism, digest it into small peptide fragments, and then combine these antigenic fragments together with MHC proteins. Once the APC has formed the antigen/MHC complex, the APC places the complex on its surface. This surface complex can then be recognized by the T-cell receptor on the surface of a T lymphocyte. The recognition of the antigen/MHC complex by the T-cell receptor is the first step in the activation of the T lymphocyte (Fig. 95–3). Other cells, B lymphocytes and mast cells, can also act as APCs (Fig. 95–4).[17–19]

Mast cells and basophils act primarily by releasing inflammatory mediators. Mast cells are tissue cells predominately associated with IgE-mediated inflammation. They are especially abundant in the skin, lungs, nasal mucosa, and connective tissue. Granules within the mast cells contain large amounts of preformed mediators that include histamine, heparin, and serotonin. Mast cells can also phagocytize, destroy, and present bacterial antigens to T lymphocytes.[18] Basophils are similar to mast cells because they contain granules filled with histamine, but they are typically found circulating in the blood and are not found in connective tissue. Like mast cells, basophils also express high-affinity IgE Fc receptors (Fcε). IgE- mediated anaphylaxis (type I hypersensitivity; Chap. 97) is caused by the stimulation of mast cell and/or basophil degranulation and the release of preformed mediators after allergen binds to IgE bound to the Fcε receptor on the surface of mast cells or basophils.[19]

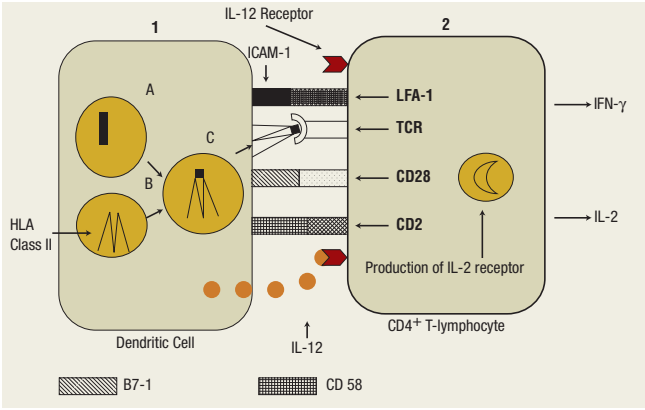

FIGURE 95-3. Induction of T-helper type 1 (TH_1) response. *1*. The antigen-presenting cell, in this case a dendritic cell, engulfs the pathogen by any of numerous cell surface receptors (see Fig. 95–2). After phagocytosis of the bacteria by the dendritic cell (A), the pathogen is digested into small peptides and become associated with major histocompatibility (MHC) class II within the endosome (B). Finally, the MHC class II plus peptide is expressed on the surface of the dendritic cell (C). The activated dendritic cell also secretes interleukin (IL)-12. *2*. Naïve $CD4^+$ T-lymphocyte activation requires the T-cell receptor (TCR) to recognize the antigenic peptide in association with MHC class II as well as the B7-1 (CD80) binding to CD28. The binding of CD2-CD58 and LFA-1 (CD11a/CD18) allows adherence between the T lymphocyte and dendritic cell. Upon activation, the TH_1 $CD4^+$ T lymphocyte secretes IL-2 and interferon (IFN)-γ and increases the production and expression of the IL-2 receptor. (ICAM, intercellular adhesion molecule.)

Soluble Mediators of the Innate Immune System

Soluble mediators of innate immunity include the complement system, mannose-binding lectin, antimicrobial peptides, and C-reactive protein (CRP).[9] The complement system consists of more than 30 proteins in the plasma and on cell surfaces that play a key role in immune defense. The four major functions of the complement system include (1) to lyse certain microorganisms and cells, (2) to stimulate the chemotaxis of phagocytic cells, (3) to coat or opsonize foreign pathogens which allows phagocytosis of the pathogen by leukocytes expressing complement receptors, and (4) to clear immune complexes. Complement factors (C3a, C5a) act as chemotactic factors for phagocytic cells.[20] Two different pathways stimulate the complement cascade. In the *classic pathway*, antibody binds to its target antigen and activates the first component of complement (C1), thereby initiating the complement cascade. The *alternative complement pathway* relies on the inability of microorganisms to clear spontaneously produced C3b, the active form of third complement protein, from their surface. Patients with hereditary deficiencies of complement have recurrent bacterial infections or immune complex disease because C3b plays a central role in opsonizing bacteria and clearing immune complexes. Both mannan-binding lectin and C-reactive protein are acute-phase reactants produced by the liver during the early stages of an infection. They bind to infectious pathogens that prompt the activation of the lectin or minor pathway of the complement system. Mannan-binding lectin binds to mannose-rich glycoconjugates on microorganisms while C-reactive protein binds to phosphorylcholine on bacterial surfaces.[9,20]

Chemokines play an essential role in linking the innate and adaptive immune response by orchestrating leukocyte trafficking. The chemokine system consists of a group of small polypeptides and their receptors. Chemokines possess four conserved cysteines. Based on the positions of the cysteines, almost all chemokines

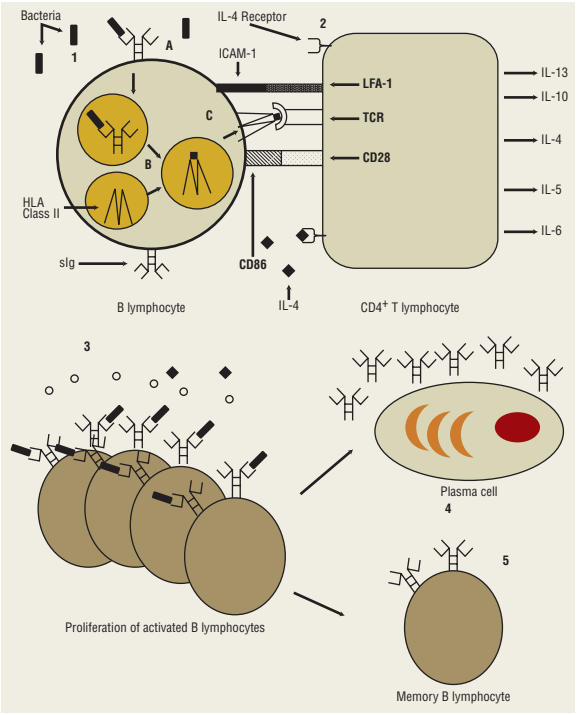

FIGURE 95-4. Induction of T-helper type 2 (TH_2) response. *1A.* A B lymphocyte recognizes invading bacteria via its surface immunoglobulin (sIg). *1B.* The bound bacteria are phagocytosed into an endosome, where the bacteria are broken down into small peptide fragments. *1C.* The small peptide fragments are placed within major histocompatibility complex (MHC) class II molecules and transported to the surface of the B lymphocyte for antigen presentation to a $CD4^+$ T lymphocyte. *2.* $CD4^+$ T-lymphocyte recognition requires antigen recognition within the MHC class II peptide groove by the T-cell receptor (TCR) and a secondary signal from B7-2 from the antigen-presenting cell, in this case a B lymphocyte, binding to CD28 on the T lymphocyte. When both signals are delivered, the $CD4^+$ T lymphocyte becomes activated. In the TH_2 environment (see text), the naive $CD4^+$ T lymphocyte develops into a TH_2 subtype and secretes interleukin (IL)-4, IL-5, IL-6, IL-10, and IL-13, which promote a TH_2 response. *3.* In the presence of these cytokines plus antigen binding to the sIg, the B lymphocyte becomes activated. The activated B lymphocyte becomes a plasma cell *(4),* which produces and secretes immunoglobulin or becomes a memory B lymphocyte *(5).* A minority of B lymphocytes become memory B lymphocytes.

fall into one of two categories: (1) CC group in which the conserved cysteines are contiguous or (2) CXC subgroup in which the cysteines are separated by some other amino acid ("X"). As with all ligand-receptor interactions, a cell can only respond to a chemokine if the cell possesses a receptor that recognizes the chemokine. Chemokine receptors are unique in that they traverse the membrane seven times. CC receptors (CCR) and CXC receptors (CXCR) bind CC ligands (CCL) and CXC ligands (CXCL), respectively (Table 95–4).

Binding of infectious pathogens to pattern recognition receptors stimulates the release of chemokines such as macrophage inflammatory protein (MIP)-1α, MIP-1β, MIP-3α, and IP-10 from macrophages and dendritic cells embedded in the tissues. These chemokines attract more immature dendritic cells to the site of inflammation/infection. Immature dendritic cells constitutively express CCR1, CCR5, and CCR6. The interaction between pattern recognition receptors on the dendritic cell to the infectious pathogen causes the activation and maturation of the dendritic cell. After activation, dendritic cells downregulate the expression of CCR1, CCR5, and CCR6 and upregulate the expression of CCR7. This switch in chemokine-receptor expression results in the antigen-loaded dendritic cell leaving the tissue and migrating toward the lymph nodes.[21]

TABLE 95-4 Common Chemokines

Receptor	Cell Expression	Ligand
CCR1	Immature DC	MIP-1α, MIP-1β, MCP-2, RANTES
CCR3	Eosinophils, basophils	Eotaxin-1, eotaxin-2, eotaxin-3, MCP-4
CCR6	Immature DC	Exodus-1
CCR7	Activated DC	CCL21 (SLC), CCL19 (ELC)
CXCR1/2	Neutrophils	IL-8
CXCR3	Natural killer cells, activated T lymphocytes	IP-10

DC, dendritic cell; MCP, monocyte chemoattractant protein; RANTES, Regulated upon Activation Normal T lymphocyte Expressed and Secreted.

Naturally occurring antimicrobial peptides include α-defensins, β-defensins, and cathelicidins. These peptides exhibit antibacterial, antifungal, and antiviral activity. Human antimicrobial peptides range in size from 29 to 37 amino acid residues in length. Neutrophils are rich source of both α- and β-defensins as well as cathelicidins. Other sources of the human antimicrobial peptides include keratinocytes, paneth cells of the intestinal and genital tracts, and epithelial cells of the pancreas and the kidney. These peptides can be induced at sites of inflammation or can be constitutively produced. The clinical interest in human antimicrobial peptides centers on their broad spectrum activity and their rapid onset of killing. They are believed to work by disrupting microbial membranes. An active area of research is how these peptides discriminate between microbial and host membranes.[22]

ADAPTIVE IMMUNE SYSTEM

Adaptive Immune Response: Antigen Recognition

The body will generally employ both the innate and adaptive immune responses to rapidly kill foreign pathogens.[9] The greatest difference between the innate and adaptive immune responses is in specificity and memory, characterized by antigen-specific receptors located on the surface of B and T lymphocytes.[11] The adaptive immune response also secretes cytokines to further amplify the innate immune response. The adaptive immune response can evolve with each subsequent infection whereas the innate response stays the same with each infection. During B- and T-lymphocyte development, an individual B or T lymphocyte rearranges its immunoglobulin and T-cell receptor genes, respectively, to produce a unique immunoglobulin or T-cell receptor, respectively. This DNA rearrangement generates enough B or T lymphocytes to recognize an estimated 10^{15} antigens.

The adaptive immune response can be divided into two major arms: humoral and cellular mediated. The humoral response is so denoted because it was discovered that the factors that provided the immune protection could be found in the "humor" or serum. B lymphocytes comprise the humoral arm. Activated B lymphocytes can differentiate into plasma cells that secrete immunoglobulin or memory B cells specific for each pathogen. T lymphocytes constitute the cell-mediated arm of the adaptive system. The immune protection provided by T lymphocytes cannot be transferred by serum alone. Rather, it is essential to actually have T lymphocytes present, thus the term cell-mediated immunity. T lymphocytes are specially tailored to defend against infections that are intracellular, such as viral infections, whereas

B lymphocytes secrete antibodies that can neutralize pathogens prior to their entry into host cells.

Adaptive Immune Response: Cells Which Mediate Antigen Recognition

The role of the T lymphocyte is to search and destroy pathogens that infect and replicate intracellularly. When these pathogens enter a cell they are no longer vulnerable to innate host defenses; therefore, it is critical that the T lymphocytes be able to distinguish which cells are infected and which cells are not. ❸ T lymphocytes do not recognize intact antigens, such as a bacterial cell wall. T lymphocytes only recognize processed antigens in association with MHC.

The *major histocompatibility complex*, a cluster of genes found on chromosome 6 in humans, is also known as the human leukocyte antigen (HLA) complex. The MHC is used by the immune system to distinguish self from non-self and provides a so-called immunologic "fingerprint." The genes from this complex encode for molecules that play a pivotal role in immune recognition and response. The MHC complex is divided into three different classes: I, II, and III. The molecules encoded by class I HLA genes include HLA-A, HLA-B, and HLA-C antigens. These molecules can be found on all nucleated cells within the body, as well as on platelets. Class I antigens are not found on mature red blood cells. Molecules encoded by class II HLA genes include HLA-DP, HLA-DQ, and HLA-DR. The expression of these molecules is more restricted and can be found primarily on cells of the immune system, namely antigen-presenting cells such as macrophages, dendritic cells, and B lymphocytes. The class III HLA antigens encode for soluble factors, complement, and tumor necrosis factors.[23] In order for a $CD4^+$ T lymphocyte to become activated, $CD4^+$ T lymphocyte must recognize the antigenic peptide in association with MHC class II (Figs. 95–3 and 95–4). $CD8^+$ T lymphocytes recognize antigenic peptide in association with class I molecules. Class I molecules generally contain endogenous peptides from within the cell, such as those derived from viruses, while class II molecules contain exogenous peptides from antigen that has been phagocytosis and digested, such as bacterial peptides (Fig. 95–3). For it to destroy a virally infected cell, a $CD8^+$ cytotoxic T lymphocyte requires two steps. First, its T-cell receptor must recognize the antigenic fragment, such as a viral protein, in association with MHC class I. The second step involves the co-stimulatory step of B7-CD28 binding. This process is further defined below. Because any cell can become infected, it is advantageous that the $CD8^+$ cytotoxic T lymphocytes recognize the MHC class I molecule that is expressed on all cells except red blood cells. The ability of the MHC class I to present endogenous peptides allows the $CD8^+$ cytotoxic T lymphocytes to constantly screen cells for infections.[23,24] Dendritic cells and macrophages demonstrate the unique capacity to direct exogenous antigens toward MHC class I molecules, a process termed cross-presentation.[25]

APCs (e.g., macrophages, dendritic cells) engulf the pathogen, digest it, and express its peptide fragments on their cell surface in association with their MHC. T lymphocytes use a specific antigen receptor, T-cell receptor (TCR), to propagate the immune response. The TCR is comprised of two chains with each chain having a variable and a constant region. The variation of the amino acid sequence within the variable domain of TCR gives the cell its unique antigen specificity. Linked to the TCR is a complex of single chains known as the CD3 complex.[9,19]

Naïve T lymphocytes, are cells that have not been previously exposed to an antigen specific for their TCR. These cells require two signals for activation. The first signal for activation involves the T lymphocyte recognizing both the processed antigen and the MHC molecule complex. The second signal involves the interaction of the B7-1 (CD80) or B7-2 (CD86) molecule on the APC with the CD28 molecule on the surface of the T lymphocyte (Figs. 95–3 and 95–4). Without the second signal, the naïve T lymphocyte becomes anergic or inactive. Memory T lymphocytes are less dependent on the second signal than are naïve T lymphocytes. CD28 is expressed on both resting and activated T lymphocytes while CTLA-4, a second ligand for B7 on T lymphocytes, is expressed only on activated T lymphocytes. CTLA-4 binding B7 transduces a negative signal so it plays a role in downregulating a T-lymphocyte response.[26] After the two activation signals, a message is sent through the TCR to the CD3 complex into the cell. Then a calcium influx occurs with subsequent activation of the T lymphocyte. Activated $CD4^+$ T lymphocytes begin to express the high-affinity IL-2 receptor and to release multiple soluble factors (e.g., IL-2) to stimulate T lymphocytes and other cells of the immune system (Fig. 95–3). Autocrine stimulation by IL-2 leads to the proliferation of the activated T lymphocyte.

Cell surface markers delineate the functional activity of T-lymphocyte populations. All T lymphocytes express the CD3 protein. Typically, T lymphocytes are further divided into helper cells ($CD4^+$), suppressor cells ($CD8^+$), and cytotoxic cells ($CD8^+$). Each of the subclasses appears to play a distinct role in the cell-mediated immune response. Naïve T lymphocytes express CD45RA, a high-molecular-weight isoform of CD45, while memory T lymphocytes express CD45RO, a lower-molecular-weight isoform of CD45.[27] The primary role of $CD4^+$ cells is to stimulate other cells in the immune response. Functionally, $CD4^+$ cells can be divided into TH_1 and TH_2. This functional system was first described in mice. TH_1 cells secrete IL-2 and γ-interferon and stimulate $CD8^+$ cytotoxic cells, whereas TH_2 cells secrete IL-4, IL-5, and IL-10 and stimulate B-lymphocyte production of antibody.[28] Multiple factors determine whether a naïve $CD4^+$ T lymphocyte develops into a TH_1 or a TH_2 cell. The cytokine microenvironment plays an important role in this development. IL-12 secreted by the APCs promotes TH_1, whereas IL-4 promotes TH_2 development. Other factors that promote TH_1 development include B7-1 (CD80), high-affinity of the TCR for the antigen, γ-interferon, and α-interferon. Factors that promote TH_2 development include B7-2 (CD86), low-affinity of the TCR for the antigen, IL-10, and IL-1.[29]

$CD8^+$ T lymphocytes recognize antigen in association with MHC class I. $CD8^+$ cytotoxic cells are instrumental in killing cells recognized as foreign, such as those that have become infected by a virus. $CD8^+$ cytotoxic T lymphocytes also play an important beneficial role in the eradication of tumor cells, but moreover are responsible for rejection of transplanted organs.[19] Classically, a second type of $CD8^+$ T lymphocytes was a suppressor cell. It is clear that some T lymphocytes help suppress the immune responses, but whether this subset is $CD8^+$ is debatable. Emerging evidence is leading away from $CD8^+$ T lymphocytes toward $CD4^+$, $CD25^+$ T lymphocytes in maintaining self-tolerance. The preferred term for these suppressive T lymphocytes is regulatory T lymphocytes.[30]

To fully activate the $CD8^+$ cytotoxic T lymphocyte requires $CD4^+$ T lymphocyte activation, namely the TH_1 subset, and its subsequent secretion of IL-2 (Fig. 95–5a). This model of $CD8^+$ cytotoxic T lymphocyte activation requires the close proximity of two-antigen specific T lymphocytes. In addition, some $CD8^+$ cytotoxic T-lymphocyte responses can occur in the absence of $CD4^+$ T lymphocytes. New data suggests that $CD4^+$ T-lymphocytes can activate/prime APCs through CD40. This interaction primes the APC (e.g., dendritic cell) to fully activate $CD8^+$ cytotoxic T lymphocytes (Fig. 95–5b).[31] It is important to remember that the classification of $CD4^+$ lymphocytes as T-helper lymphocytes and $CD8^+$ lymphocytes as T-cytotoxic lymphocytes is not an

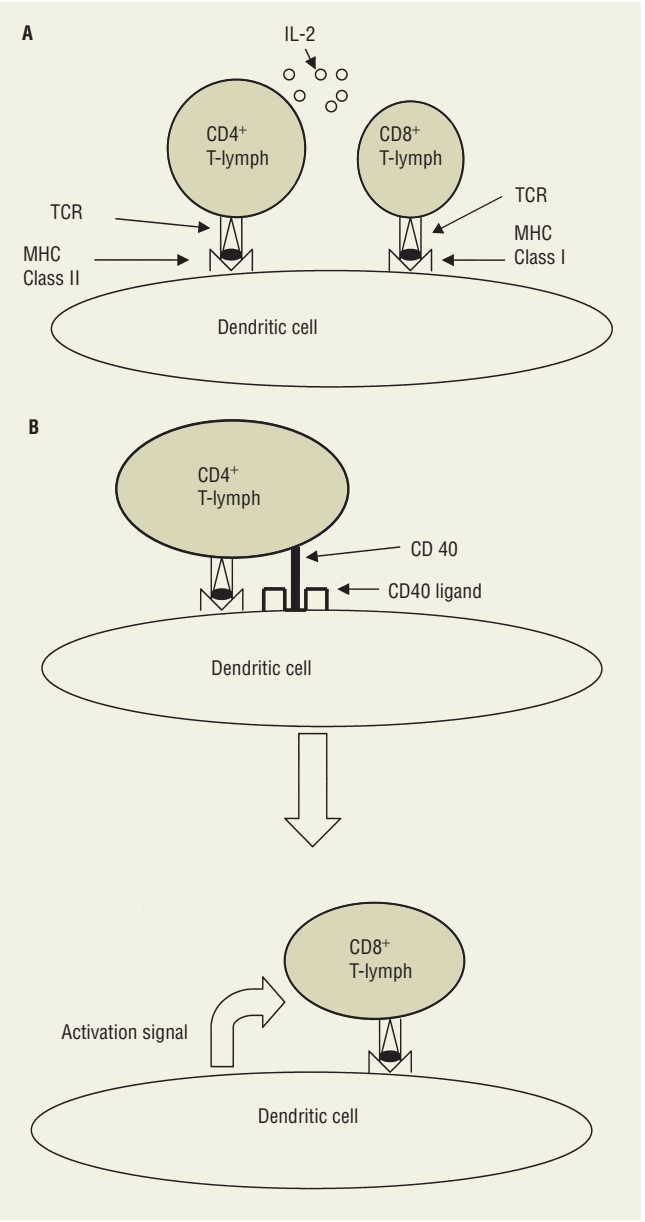

FIGURE 95-5. In the classic model of $CD8^+$ T-lymphocyte activation *(A)*, $CD4^+$ and $CD8^+$ T lymphocytes recognize antigen on the same dendritic cell. In the presence of interleukin (IL)-2 from the activated $CD4^+$ T lymphocyte and the recognition of antigen in association with major histocompatibility complex (MHC) class I, the $CD8^+$ T lymphocyte becomes activated. In the new model *(B)*, activated $CD4^+$ T lymphocytes activate dendritic cells via CD40 ligand binding to CD40. The activated dendritic cell then migrates through the tissues to present antigen to $CD8^+$ T lymphocytes. If recognition via the T-cell receptor (TCR) on the $CD8^+$ T lymphocyte occurs, the dendritic cell can fully activate the $CD8^+$ T lymphocyte without the presence of $CD4^+$ T lymphocytes.

absolute. Some $CD8^+$ T lymphocytes secrete cytokines similar to a T-helper lymphocyte, and some $CD4^+$ T lymphocytes can act as cytotoxic cells.

Unlike neutrophils and macrophages, cytotoxic T lymphocytes are unable to ingest their targets. They destroy target cells by two different mechanisms: the *perforin system* and the *Fas ligand pathway*. After recognition by the cytotoxic T lymphocyte, cytoplasmic granules containing perforins and granzymes are rapidly oriented toward the target cell, and the contents of the granules are released into the intracellular space. Like the membrane attack complex formed after complement activation, perforins form a pore in the target cell membrane. Besides a direct cytotoxic effect on the target cell, the pores produced by perforins allow the granzymes to penetrate into the target cell to induce apoptosis. The second mechanism of cytotoxicity involves the binding of Fas ligand on the cytotoxic T lymphocyte to the Fas receptor on the target cell. The Fas ligand is predominately expressed on $CD8^+$ cytotoxic T lymphocytes and NK cells, and its expression increases after activation. After destroying that target cell by either mechanism, the cytotoxic T lymphocyte detaches from the target cell and attacks other targets.[32]

A B lymphocyte recognizes antigen via its antibody or immunoglobulin located on its cell surface (Fig. 95–4). The antibody on the surface can recognize an intact pathogen, such as bacteria, and present antigen to T lymphocytes (i.e., acting as APC). However, the major function of B lymphocytes is to produce antibody to bind to the invading pathogen, a process that first entails activation of the B lymphocyte. The activation of B lymphocytes also requires two steps: (1) recognition of antigen by the surface immunoglobulin and (2) the presence of B-lymphocyte growth factors (IL-4, -5, -6) secreted by activated $CD4^+$ T lymphocytes. Once activated, the B lymphocyte becomes a plasma cell, a differentiated cell capable of producing and secreting antibody. A fraction of activated B lymphocytes do not differentiate into plasma cells, but rather form a pool of memory cells. The memory cells will respond to subsequent encounters with the pathogen, generating a quicker and more vigorous response to the pathogen. Some B lymphocytes can become activated without help from T lymphocytes, but these responses are generally weak and do not invoke memory.[9,19]

Natural killer (NK) cells, often referred to as large granular lymphocytes, are defined functionally by their ability to lyse target cells without prior sensitization and without restriction by MHC. Resting NK cells express the intermediate-affinity IL-2 receptor, CD122. Upon exposure to IL-2, NK cells exhibit greater cytotoxic activity against a wide variety of tumors. NK cells recognize target cells by two mechanisms. First, NK cells express an IgG Fc receptor, CD16 that allows recognition of IgG-coated cells. Second, NK cells express killer-activating and killer-inhibiting receptors. The killer-activating receptors recognize multiple targets on normal cells; however, the binding of MHC class I to the killer-inhibitor receptor blocks release of perforins and granzymes. Therefore, cells (e.g., tumor cells, virally infected cells) that downregulate MHC class I expression are susceptible to NK cell cytolysis. NK cells play important roles in the surveillance and the destruction of tumors and virally infected host cells, and in the regulation of hematopoiesis.[9,33]

Soluble Mediators of the Adaptive Immune Response

4 When binding of a specific antigen to the surface immunoglobulin receptor of B lymphocytes occurs, the B lymphocyte matures into a plasma cell and produces large quantities of antibody that have the ability to bind to the inciting antigen. The secreted antibodies may be of five different isotypes. On primary exposure to the pathogen, the plasma cell will secrete IgM; then, eventually, there is a switch to predominately IgG. On second exposure, the memory B lymphocytes will predominately produce IgG. Isotype switching from IgM to IgG, IgA, or IgE is controlled by T lymphocytes.

An antibody or immunoglobulin is a glycoprotein comprised of two different chains, heavy and light (Fig. 95–6). The basic structure of every immunoglobulin consists of four peptide chains: two identical heavy chains and two identical light chains held together by disulfide bonds. The basic structure of the antibody is a Y-shaped figure. Each arm of the Y is formed by the linkage of

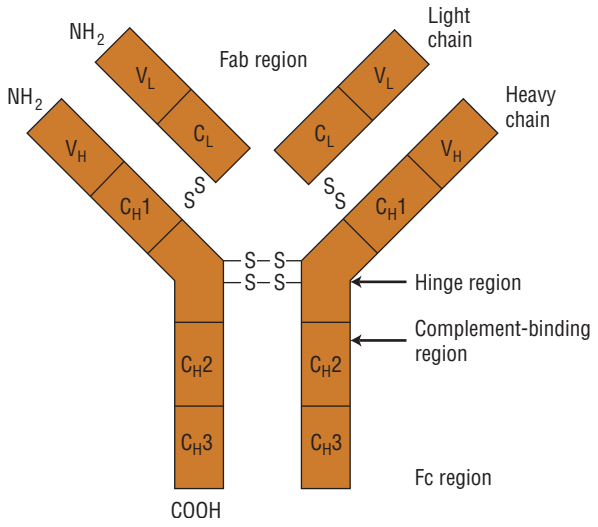

FIGURE 95-6. Schematic diagram of the structure of the immunoglobulin G (IgG) molecule. IgG molecule consists of two heavy (H) and two light (L) chains covalently linked by disulfide bonds. Each chain is composed of variable (V) and constant (C) regions. A light chain consists of one variable (V_L) and one constant (C_L) region. Heavy chains consist of one variable (V_H) and three or four constant (C_H) regions, depending on the isotype. The variable regions (V_L and V_H) compose the antigen-binding region of the IgG molecule, or fragment antigen binding (Fab). The constant regions provide the structure to the IgG molecule as well as binding the first component of complement (C_H2) and binding to Fc receptors via the Fc portion of the molecule (C_H3).

the end of the light chain to its heavy chain partner. These arms contain the portions described as the *fragments of antigen binding (Fab fragments)*. The stem of the Y contains the heavy chains which comprise the *fragment crystallizable (Fc fragment)* portion of the antibody. It is within the Fc portion that complement is activated once the antibody has bound its target. Likewise, it is the Fc portion of the antibody that is recognized by Fc receptors on the surface of phagocytes (Fig. 95–2). The amino acid composition of the same isotype is homogenous except in the variable regions of the light (V_L) and heavy chains (V_H). The variation in amino acid composition of the variable region gives the antibody its unique specificity (Fig. 95–6).

IgG, the most prevalent of the antibody classes, comprises approximately 80% of serum antibody. IgG is usually the second isotype of antibody to be produced in an initial humoral immune response. IgG is the only isotype of antibody that can cross the placenta. Therefore, early maternal humoral protection of neonates is primarily due to maternal IgG that crossed the placenta in utero.

Four different subclasses of IgG have been described: IgG1, IgG2, IgG3, and IgG4. These subclasses differ slightly in their constant amino acid sequences. IgG1 constitutes the majority (60%) of the subclasses. It appears that different subclasses recognize different types of antigen. IgG1 and IgG3 are principally responsible for recognition of protein antigens while IgG2 and IgG4 commonly bind to carbohydrate antigens. Another difference in the subclasses is the ability to activate complement with IgG3 and IgG1 being the most efficient, but IgG4 is unable to activate the complement system.

IgM can be found on the surface of B lymphocytes as a monomeric Y-shaped structure. In contrast, secreted IgM is a pentamer in which five of the monomers are joined together by a joining chain (J-chain). IgM is the first class of antibody to be produced on initial exposure to an antigen. Because the pentameric form of IgM has no Fc portions exposed, phagocytic cells cannot bind pathogens opsonized by IgM. However, IgM is an excellent activator of the complement cascade by the classic pathway.

IgA is found primarily in the fluid secretions of the body: tears, saliva, nasal fluids; and also in the gastrointestinal, genitourinary, and respiratory tracts. IgA functions by preventing pathogens from adhering to and infecting the epithelial cells at these sites. IgA is also secreted in a nursing mother's breast milk as well as are IgG and IgM but in lower concentrations. In bodily secretions, IgA is in a dimeric form in which a J-chain and a secretory chain hold two monomers together. The dimeric form is resistant to proteolysis in mucosal secretions.

IgD is the least understood isotype. IgD is found on the surface of B lymphocytes at different stages of maturation and may be involved in the differentiation of these cells. The main function of circulating IgD has not yet been determined. However, mice treated with exogenous anti-IgD antibody display a marked increase in immunoreactivity and secretion of all types of immunoglobulins and several T-cell specific cytokines. High levels of anti-IgD autoantibodies of various subtypes have also been observed in most autoimmune diseases with frequencies of >50%, suggesting that IgD may play an important role in the etiology of these diseases.[34]

IgE is the least common of the serum antibody isotypes. Most of the IgE in the body is bound to the IgE Fc receptors on mast cells. When the IgE on the surface of mast cells binds antigen, it causes the release of various inflammatory substances (e.g., histamine) from the mast cell. The overall effect is the stimulation of inflammation. Asthma and hay fever are two examples of allergic reactions primarily due to antigen binding to IgE.[29]

Cytokines are soluble factors released or secreted by cells. These proteins affect the activity of other cells (paracrine) or the secreting cell itself (autocrine). For example, activated $CD4^+$ T lymphocytes secrete IL-2 which activates itself as well as activating $CD8^+$ T lymphocytes and NK cells. Research has shown that many cytokines (Table 95–5) have a broad spectrum of effects dependent on their concentration, the presence of other factors, and the target cell. New cytokine families and their roles in disease processes are being discovered daily. Cytokines provide communication between the divisions of the immune system. Cytokines produced from APCs generally promote chemotaxis of other cells and induce a state of inflammation.[35] Monocytes, as previously mentioned, use pattern recognition receptors, enabling the immune system to distinguish pathogenic proteins from nonpathogenic proteins through toll-like receptors stimulating T-lymphocyte activation.[35] Cytokines can also prevent activation or response of immunologic cells. For example, IL-10 is an anti-inflammatory cytokine that is produced in the respiratory tract to prevent IgE synthesis and activation of eosinophils when exposed to benign inhaled particles.[35] In vivo cytokines do not act alone but in combination with other cytokines. For example, activated $CD4^+$ T lymphocytes secrete both IL-2 and interferon-γ which are synergistic in activating NK cells. As shown in Tables 95–1 and 95–5, cytokines are broadly classified as regulatory or hematopoietic growth factors.[19,36–40] This classification does not describe all their activities. Granulocyte macrophage-colony stimulating factor (granulocyte-macrophage colony-stimulating factor) released by activated T lymphocytes acts as a hematopoietic growth factor, but also activates granulocytes and macrophages to phagocytize foreign pathogens.

The division of the immune system into the two functional groups does not imply that the divisions do not interact. In order to generate a vigorous immune response, both soluble mediators (e.g., complement, antibody, and cytokines) and cells (e.g., neutrophils, macrophages, dendritic cells, T lymphocytes, and B lymphocytes) are needed. Generally, the innate system will respond first. Dendritic cells, macrophages and neutrophils in the tissues

TABLE 95-5 Cytokines

Cytokines	Sources	Principal Effects
Regulatory		
IL-1	Macrophages, fibroblasts, endothelial cells	Activation of T and B lymphocytes, hematopoietic growth factor, induction of inflammatory events
IL-2	$CD4^+$ T lymphocytes (TH_1 subset)	Activation of T lymphocytes, B lymphocytes, NK cells
IL-4	$CD4^+$ T lymphocytes (TH_2 subset), mast cells, basophils, eosinophils	B- and T-lymphocytes growth factor, activation of macrophages, promotes IgE production, proliferation of bone marrow precursors
IL-5	$CD4^+$ T lymphocytes (TH_2 subset), mast cells	Activation of B lymphocytes and eosinophils, promotes IgE production
IL-6	$CD4^+$ T lymphocytes (TH_2 subset), macrophages, mast cells, fibroblasts	T- and B-lymphocyte growth factor, hematopoietic growth factor, augments inflammation
IL-8	T lymphocytes, monocytes, endothelial cells, fibroblasts	Neutrophil, basophil, T-lymphocyte chemotaxis
IL-10	T and B lymphocytes, macrophages	Cytokine synthesis inhibitory factor, growth of mast cells
IL-12	Macrophages, neutrophils, dendritic cells	Induce TH_1 cells, ↑ NK cell activity, ↑ generation of cytotoxic T lymphocytes
IL-13	Activated T lymphocytes	Proliferation of B lymphocytes, suppression of proinflammatory cytokines, directs IgE isotype switching
IL-14	T lymphocytes	Induces B-lymphocyte proliferation, inhibits secretion of Igs
IL-15	Macrophages, fibroblasts, dendritic cells, epithelial cells	T-lymphocyte proliferation, activation of NK cells
IL-16	$CD8^+$ T lymphocytes, epithelial cells	Chemoattractant for $CD4^+$ T lymphocytes and eosinophils; stimulation of secondary cytokine secretion from and proliferation of $CD4^+$ T lymphocytes
IL-18	Macrophages	Induces IFN-γ production
IL-28, IL-29[a]	Antigen-presenting cells, but proposed that all nucleated cells may produce	Alternative to IFN-α/IFN-β to provide immunity against viral infections by inhibiting viral replication
IL-31	Activated T lymphocytes	Involved in recruitment of polymorphonuclear cells, monocytes, and T cells to site of inflammation
IL-32	NK cells, T lymphocytes, epithelial cells	Induces proinflammatory cytokines including TNF-α and IL-8
TNF-α	Macrophages, NK cells, T and B lymphocytes, mast cells	Activation of neutrophils, endothelial cells, lymphocytes, liver cells to produce acute phase proteins
TNF-β	T lymphocytes	Tumoricidal
IFN-α	Monocytes, other cells	Antiviral, activation of NK cells and macrophages, upregulation of MHC class I
IFN-γ	T lymphocytes, NK cells	Activation of macrophages, NK cells, upregulation of MHC class I and II

IFN, interferon; Ig, immunoglobulin; IL, interleukin; MHC, major histocompatibility complex; NK, natural killer; TNF, tumor necrosis factor.
[a] Also known as the new type III IFN-λ family.

will recognize pathogen via surface receptors (Fig. 95–2). In order to amplify the immune response, the antigen presenting cells will present antigen to $CD4^+$ T lymphocytes (Figs. 95–3 and 95–4). The activated $CD4^+$ T lymphocytes will then secrete cytokines to activate B lymphocytes, $CD8^+$ T lymphocytes, NK cells, macrophages, and neutrophils. The next section of the chapter discusses the evaluation of the immune system.

DISEASES OF THE IMMUNE SYSTEM

Although this chapter is not intended to detail the diseases of the immune system, it is necessary to review the terminology and provide specific examples of diseases of the immune system to understand the role of monitoring and possible intervention with pharmacotherapy. Diseases of the physical defense immune system are often not thought of as diseases of the immune system; however, the loss of normal physical defenses is the most common cause of impaired immunity resulting in infectious sequelae. For example, thick respiratory secretions secondary to altered chloride transport in cystic fibrosis leads to pathogen airway colonization. Primary immunodeficiency diseases are those characterized by either a genetic inability to produce components of the immune system (i.e., severe combined immunodeficiency or hypogammaglobulinemia) or acquired, as seen with HIV infection. Autoimmune diseases result from a dysregulation of a component or a combination of components of the immune system (e.g., rheumatoid arthritis, systemic lupus erythematosus).[41] Autoimmune diseases are often characterized by production of autoantibodies against a particular host structure that is critical for normal function, or loss of tolerance or anergy to a ubiquitous antigen (i.e., gluten in celiac sprue).[41] Often medications that suppress the immune system are necessary to control symptoms and halt autoimmune disease progression. Exposure to immunosuppressant medications in the setting of autoimmune diseases or organ transplantation may reduce disease symptoms but at the cost of the host's ability to fight off infection or cancer. Exogenous regulation of the immune system must be done judiciously, and we must continue to discover new methods for the appropriate evaluation of immune responses.

EVALUATION OF THE IMMUNE SYSTEM'S FUNCTION

Assessment of a patient's immune function requires knowledge and understanding of multiple components including mechanical defenses, cell phenotypes and cell numbers, and soluble components. Recent developments in biotechnology have allowed for progress in further characterization of immune system components and their functions. This is important because the upregulation and downregulation of immune responses is necessary to treat various disease states. Therefore, pharmacotherapeutic considerations must balance the risk of disrupting normal immunologic homeostasis. Improvements in immune monitoring are necessary for the goal of patient-specific immunologic pharmacotherapy. Despite the technological advances, careful patient evaluations are required to accurately assess the structure and function of the immune system. Specific methods for assessment of patient immune status are discussed below.

TABLE 95-6 Examples of Alteration in Mechanical Immunodefenses That Result in Impaired Immune Status

- Reduced gastric pH
  - Achlorhydria
  - Use of histamine-2 blockers and proton pump inhibitors
  - Patients with acquired immunodeficiency syndrome
- Break in skin barrier
- Burns
  - Surgical incision
  - Penetrating trauma
  - Vascular access devices
- Impaired mucociliary function of the lungs
  - Smoking
- Impaired esophageal or epiglottal function
  - Endotracheal intubation
  - Stroke
  - Recumbent position
- Altered urine flow
  - Urinary stones
  - Anatomic deformities obstructing flow
  - Bladder catheter
- Anatomic alterations of the heart resulting in turbulent blood flow and endocarditis

INNATE IMMUNITY: EVALUATION OF MECHANICAL IMMUNODEFENSES

As discussed earlier, the mechanical aspects of host defense are extremely important in protection from infection; therefore, assessment of mechanical defenses is critical. Much of the assessment of mechanical immunodefense is accomplished by recognition of situations where such defense is compromised. Careful patient examination usually reveals the extent of compromise, and laboratory tests are generally not necessary for evaluation of this component. To assess the extent of compromise in mechanical immunodefenses, the clinician should carefully examine the patient and identify the specific types of risks present. Specific examples of altered mechanical defenses are listed in Table 95–6.

INNATE AND ADAPTIVE IMMUNITY: GROSS EVALUATION OF CELLULAR COMPONENTS

A major aspect of the assessment of immune function relates to the cells of the immune system. Assessment of cells in the clinical setting includes determination of cell type, cell number, and/or function. Generally, determination of the cell types and quantification of the cell numbers are performed first because of the ease of obtaining these results and the common correlation with the clinical situation.

To quickly screen cell numbers, a *white blood cell (WBC) count* with differential is performed. Normal cell counts are shown in Table 95–7.[42] This simple test often steers the differential diagnosis. In interpreting a WBC with differential, the clinician must consider several factors. A normal cell count does not mean that a leukocyte disorder does not exist. For example, in chronic granulomatous disease, a child has a normal neutrophil count, but the neutrophils are unable to destroy the bacteria. Second, a differential is reported as percentage of the WBC; therefore, one must also assess the absolute number as well as the percentage of white cell subtypes. For example, a patient admitted to the hospital with pneumonia has an elevated WBC (15,000 cells/mm^3 [15 × 10^9/L]) with a manual differential of 70% segs, 10% bands, 15% lymphocytes, and 5% monocytes. The WBC is predominately neutrophils; segs or mature neutrophils (70%) and bands or immature neutrophils (10%). The

TABLE 95-7 Leukocyte Counts in Adults

Cell	Absolute Count (Range)[a]	Percentage (Range)[b]
White blood cells	7,500 (4,500–11,000)	100
Neutrophils	4,500 (2,300–7,700)	60 (50–70)
Eosinophils	20 (0–45)	3 (0–5)
Basophils	4 (0–20)	1 (0–2)
Monocytes	30 (0–80)	4 (0–10)
Lymphocytes	210 (160–240)	32 (28–39)
T lymphocytes	140 (110–170)	72 (67–76)[b]
$CD4^+$	80 (70–110)	42 (38–46)[b]
$CD8^+$	70 (50–90)	35 (31–40)[b]
B lymphocytes	30 (20–40)	13 (11–16)[b]
Natural killer cells	30 (20–40)	14 (10–19)[b]
CD4/CD8 ratio	1.2 (1.0–1.5)	

[a] Cell counts are expressed as cells/mm^3 or × 10^6/L.
[b] Percentage of lymphocyte subpopulations expressed as percentage of total lymphocyte population. For expression in SI units multiply each number by 0.01 to give the corresponding fraction.

percentage of lymphocytes appears low at 15% (Table 95–7), but the absolute number of lymphocytes is actually normal, 2250 cells/mm^3 (15,000 cells/mm^3 × 0.15). A third factor to consider is that the majority of lymphocytes are in secondary lymphoid organs (e.g., lymph nodes, spleen), and changes in peripheral blood lymphocytes do not always mirror changes in the secondary lymphoid organs. Additionally, the majority of granulocytes, macrophages, and mast cells are also in the tissues, not the bloodstream.

Generally, the numbers of granulocytes (neutrophils, basophils, eosinophils) and monocytes are assessed by a WBC with differential. Increased WBC counts with immature neutrophils (bands, metamyelocytes, myelocytes, and promyelocytes) in the peripheral blood is called a "shift to the left," and is abnormal. It most often indicates a bacterial infection, but also can indicate trauma or leukemia. It has long been recognized that the lower the absolute neutrophil count, the greater the risk of infection. Drugs (e.g., chemotherapy) and diseases (e.g., collagen vascular disorders) may lower the neutrophil count and make the patient more susceptible to infections. Patients with a neutrophil count below 1,500 cells/mm^3 (1.5 × 10^9/L) are considered to have neutropenia. Functional analysis of these cell types is rarely done in routine clinical practice. Patients with suspected functional deficits in these cell types are generally referred to tertiary medical centers for evaluation and treatment.

A routine WBC with differential can determine the total lymphocyte count. Total lymphocyte count has been used as a measure of nutritional status, as this rapidly changes with nutrient loss or repletion. This is a relatively gross measure of a patient's immune status although it has been correlated to patient outcome and risk of infection.

Lymphocyte populations with different functions or in various stages of activation can be enumerated based on their cell surface markers. These cell surface markers are known as clusters of differentiation (CD). The CD is usually a protein or glycoprotein on the surface of the cell. CD followed by a number designates the marker. Hundreds of monoclonal antibodies have been designed to recognize these cell surface markers. Monoclonal antibodies can be labeled with a fluorescent marker. The labeled monoclonal antibodies are then incubated with the patient's cells. The antibodies will recognize and bind to the cells expressing the CD of interest, and the cells are then counted using flow cytometry. For flow cytometry, the cell suspension is put under pressure such that the cells flow past a laser in a stream of single cells. The laser will excite the fluorescently labeled antibodies bound to the lymphocytes. A light detector is able to count the labeled cell as the fluorescent tag emits light and determines the size of the cell based on its light

TABLE 95-8 Cluster of Differentiation (CD) Guide: Characterization of Human Leukocyte Antigens

CD	Predominant Cellular Distribution
CD3	All T lymphocytes
CD4	Helper T lymphocytes, either TH_1 or TH_2
CD5	T lymphocytes, B-lymphocyte subset
CD8	Cytotoxic/suppressor T lymphocytes
CD14	Monocytes, neutrophils
CD20	B lymphocytes
CD25	Activated T lymphocytes, B lymphocytes, interleukin-2 receptor α-chain (Tac)
CD33	Committed myeloid progenitor cells
CD34	Hematopoietic progenitor cells that include the stem cell
CD56	Natural killer cells
CD83	Dendritic cells

scatter. These evaluations are valuable for assessment of patients with immune deficiency states such as AIDS or leukemias, and for patients who have received organ transplants. For example, clinically quantification of $CD3^+$ and $CD4^+$ cells are used, for example, to monitor muromonab, a monoclonal antibody directed against the CD3 receptor. Also the number of $CD4^+$ cells in HIV-positive patients correlates with the risk of and opportunistic infection and delineates the time to initiate antiviral therapy. Some of the more common CD antigens and their respective cellular distribution are listed in Table 95–8.[43] Flow cytometry can be used for leukocyte phenotyping, tumor cell phenotyping, as well as for some types of DNA analysis.

INNATE AND ADAPTIVE IMMUNITY: FUNCTIONAL EVALUATION

Counting the number of cells may help you estimate the function of the immune system, but several disease states exist in which there is an adequate number of cells but they are nonfunctional or they do not produce cytokines to communicate effectively. No single test exists to predict the function of the immune system with 100% accuracy. However, available tests can measure the viability of certain cell lines and communication between cells. Historically, the most common in vivo assay of lymphocyte function is the delayed hypersensitivity skin test. This test specifically evaluates the presence of delayed-type hypersensitivity or the presence of memory T lymphocytes. Specifically, a small amount of antigen, of which the patient is known to have been previously exposed, is administered. Under normal immunologic host conditions, exposure to this amount of antigen in the skin should produce lymphocytic infiltrate into the area within a few hours; followed by additional lymphocyte recruitment and phagocytes (e.g., macrophages, neutrophils) translocation. The maximal intensity of the inflammatory reaction occurs by 24 to 72 hours. This reaction is often referred to as type IV hypersensitivity (i.e., cell mediated; Chapter 97). A delayed-type hypersensitivity reaction is a test of cell-mediated immunity used to assess immunocompetency. The most common method to assess delayed-type hypersensitivity is to administer intradermally a panel of recall antigens. Commonly used antigens include *Candida albicans*, mumps, trichophyton, tetanus toxoid, and purified protein derivative of tuberculin (PPD).[44] Measurements in millimeters of induration at the site of injection should be taken 48 to 72 hours after placement of the antigens. A reaction is considered positive if the diameter of induration is 2 mm or greater. The degree of sensitivity correlates to the area of induration.[43] Reaction to even a single antigen indicates a functioning cell-mediated immunity. The majority of immunocompetent individuals will show a positive reaction to at least one of these antigens. Possible reasons for not mounting a response to these antigens include congenital T-lymphocyte deficiency, cancer, HIV, or immunosuppressive drug therapy.[44] No response is sometimes mounted because the individual being tested has not been previously exposed to a particular test antigen, although this is rare.

Global assessment of the in vivo immunologic response is also used commonly in solid organ transplantation during the diagnosis and assessment of acute rejection. For example, cellular rejection is detected on gross tissue biopsy by counting the number of lymphocytes present in the tissue and correlating their presence with other clinical findings, such as increasing serum creatinine in kidney transplant.

In vivo assessment of B-lymphocyte function involves immunizing the patient with a protein (e.g., tetanus toxoid) and a polysaccharide (e.g., pneumococcal polysaccharide vaccine) antigen to elicit and measure antibody responses after immunization. Two to 3 weeks after immunization, the patient's serum is tested for antibodies specific for the immunized antigen. This test measures B-lymphocyte responsiveness to the inoculated antigens but is reserved for patients who are suspected to have impaired B-lymphocyte function.[42]

A number of specific in vitro lymphocyte functional assays are used in the research setting. A few assays are performed at specialized clinical laboratories. One of these tests is the lymphocyte proliferation assay. In this assay, lymphocytes are obtained from a patient's peripheral blood and cultured in vitro. The cells are exposed to nonspecific mitogens such as pokeweed mitogen, phytohemagglutin, or concanavalin A. Then the cells are incubated in growth media containing tritium-labeled (^3H) thymidine, a nucleotide used in the synthesis of DNA. Normally in the presence of the mitogens, lymphocytes will be stimulated to proliferate. Proliferating lymphocytes will incorporate ^3H thymidine as they replicate DNA. The level of radioactivity of the cells can be measured on a β-scintillation counter and is proportional to the degree of proliferation. The patient sample needs to be compared to normal, healthy controls' lymphocytes. Patients with immune deficiencies (AIDS, cancer, etc.) have fewer active or less active lymphocytes, as detected by this test.

A modification of the lymphocyte proliferation assay can be used in allogeneic bone marrow transplantation to evaluate how closely a donor and host are "matched" in order to predict a patient's risk for developing graft-versus-host disease. A mixed lymphocyte culture (MLC) can be used to assess the potential of the donor cells to attack the host cells, graft-versus-host disease (Chap. 148). In this test, donor cells and host cells are incubated in vitro. The host lymphocytes are irradiated prior to the incubation so that they cannot proliferate. In vitro, ^3H thymidine is provided to the cells and uptake is measured. The degree of uptake correlates to level of proliferation of donor lymphocytes. If the cells are well matched, proliferation is minimal. If the cells are mismatched, proliferation will be noted with the level of proliferation predictive of the potential extent of graft-versus-host disease. With the introduction of DNA-based molecular typing of HLA antigens, the MLC is rarely used today. However, the MLC may play a role in selecting not completely histocompatible donors.[44]

The Cylex Immune Cell Function Assay was recently FDA approved as a novel test used to determine the magnitude of suppression of $CD4^+$ cells.[45] Briefly, activity of $CD4^+$ cells is measured by quantification of the amount of ATP produced and characterized as high, medium, or low.[46] Initial, retrospective experience has been reported in the solid organ transplant population. Although this assay is in its clinical infancy, it is one of the first functional assays aimed at assessing individual patient response to immunosuppressive therapy. This type of testing may allow for tailoring of immunosuppression.

More recently, evaluation of immune cell activity, such as factor forkhead box P3 (FOXP3) T-regulatory cell activity has been used to evaluate the incidence and severity of acute rejection based on elevated FOXP3 mRNA expression in urine and tissue cell samples. T-regulatory cells control autoimmune reactions; therefore, the presence of these cells in an allograft may indicate a level of "tolerance" to the donor tissue. Tolerance, basically, is a state in which the body knows that foreign tissue (e.g., kidney transplant) exists but does not attack it. Initial studies have evaluated biopsy samples from organ transplant recipient and correlated them with levels of FOXP3. Early evidence suggests that FOXP3 is present only during periods of inflammation, such as rejection, and potentially projects the allograft tissue.[47] In addition to the tests described above, a number of other tests and assays have been devised to evaluate the function of $CD8^+$ T lymphocytes, NK cells, and monocytes/macrophages. Although these evaluations are not commonly performed, they may be helpful in some specific diseases and will likely be the way in which we monitor and detect immunologic events in the future. A thorough discussion of these tests is available.[48]

EVALUATION OF CYTOKINES AND CHEMOKINES

Often disease states involving the loss or upregulation of cytokines and chemokines are overlooked as diseases of the immune system. However, as we have just reviewed, cytokines and chemokines are essential components of both the innate and adaptive immune systems and provide the communication linking them together. Assays of humoral components may be either quantitative to determine the absolute concentration of the factor or qualitative to determine the function of the component.

IMMUNOGLOBULINS

Measurement of immunoglobulins is a direct measure of B-cell function. The most common evaluation of immunoglobulins is the estimation of total immunoglobulin. This is approximated by subtracting the albumin concentration from the total protein concentration in serum. This difference gives a gross estimation of the total immunoglobulin concentration. Actual determination of the total immunoglobulin concentration is done by serum protein electrophoresis (SPEP). Five separate zones are detected by this method: albumin, α_1-globulin, α_2-globulin, β-globulin, and γ-globulin.

5 The γ-globulin fraction contains the five isotypes of immunoglobulin (i.e., IgG, IgA, IgM, IgE, and IgD). A normal total immunoglobulin or γ-globulin concentration ranges from 0.8 to 1.6 g/dL. This test is used to determine if patients have hypogammaglobulinemia (i.e., primary and secondary immunodeficiencies), a monoclonal peak (e.g., multiple myeloma, Waldenstrom macroglobulinemia), or a polyclonal hypergammaglobulinemia (e.g., chronic inflammatory conditions such as systemic lupus erythematosus or chronic active hepatitis). Total immunoglobulin or γ-globulin concentrations cannot be used to measure antigen specific antibodies or specific isotypes, although other evaluations can.

In a patient suspected of having humoral immune deficiency or B-lymphocyte failure (i.e., primary and secondary hypogammaglobulinemia), specific immunoglobulin isotypes in the plasma should be measured.

There are many indications for the measurement of antigen-specific antibody. Some common indications are listed in Table 95–9. Methods to perform these measurements include enzyme-linked immunosorbent assay (ELISA), radioimmunoassay (RIA), and radioallergosorbent test (RAST) (Fig. 95–7). The most common reason to measure antigen-specific antibody is to determine whether or not a patient has been exposed to an infectious agent. Generally, IgM antibodies directed against the pathogen indicate an active or recent infection while IgG antibodies directed against the pathogen indicate prior exposure. This observation correlates with our understanding of B-lymphocyte responses in which plasma cells produce IgM initially in response to an infection, but later switches to IgG. Therefore, IgM antibodies will be

TABLE 95-9 Potential Indications for Measurement of Antigen-Specific Antibody

Environmental or drug allergy
Exposure to or infection with bacteria
Streptococci (ASO titer)
Staphylococcus aureus (teichoic acid antibody)
Neisseria gonorrhoeae
Legionella pneumophila
Exposure to or infection with viruses
Human immunodeficiency virus
Cytomegalovirus
Epstein-Barr virus
Hepatitis A, B, or C
Rubella
Exposure to or infection with other pathogens
Syphilis
Lyme disease
Typhoid
Chlamydia
Immune disorders
Rheumatoid factor antibody, rheumatoid arthritis
Antinuclear antibodies, systemic lupus erythematosus
Platelet-associated immunoglobulin G, idiopathic thrombocytopenic purpura
Blood typing and crossmatching
Transplantation
Human leukocyte antigen (HLA) antibodies

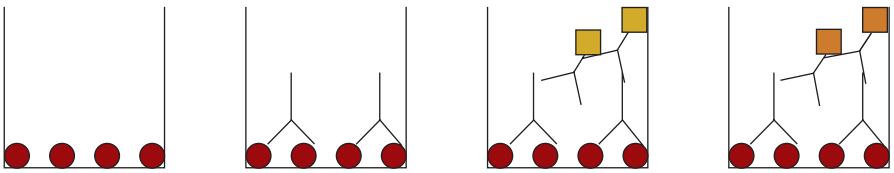

FIGURE 95-7. Enzyme-linked immunosorbent assay (ELISA). ELISA is a commonly used method for measuring concentrations of a wide variety of substances. To measure the concentration of antibodies to a particular antigen, the antigen is coated onto a solid phase, such as a microtiter plate or beads. If the purpose of the assay is to measure the concentration of antigen in solution, an antibody to the antigen is coated on the solid phase. The biologic fluid, often sera, is added to the wells. An enzyme-labeled anti-human antibody is added next. Finally, the chromogenic substrate for the enzyme is added. The intensity of the color as measured spectrophotometrically is proportional to the concentration of the antibody in the biologic fluid.

present during an active infection and shortly after recovery from the infection. IgG concentrations will increase at the end of the primary exposure, but predominate after a second exposure. IgG predominates after a second exposure because memory B lymphocytes predominately secrete IgG in the serum. Other uses of antigen-specific antibody include determining if a patient has had exposure and is likely to be protected from infection (e.g., hepatitis A virus) or to determine adequate response to vaccination (e.g., hepatitis B vaccine). Clinically, measurement of antihuman IgG antibodies is used pre- and post-solid organ transplant to detect and potentially predict allograft compatibility and treat antibody-mediated rejection.

Antigen-specific IgE is commonly measured in patients with allergies. Because the presence of antigen-specific IgE is related to clinical allergy, measurement of these antibodies can be helpful in diagnosing allergies and determining offending substances. A standard method for determination of allergen-specific IgE is the RAST. The basic technique involves adding the antigen of interest, which is bound to beads or disks, to the patient's serum. After precipitation and several washings, the antibody bound to the bead or disk is isolated. Finally, a radiolabeled antibody that binds to IgE is added. After further washings, the radiolabeled antibody bound to IgE, which is bound to the antigen on the bead or disk, is counted on a gamma counter.

Antigen skin testing is the preferred method to determine the presence of allergen-specific IgE. When it is produced, IgE binds to high-affinity IgE Fc receptors on basophils or mast cells. Contact of an allergen with the specific IgE on the basophil or mast cell surface causes activation of these cells and the release of inflammatory mediators (e.g., histamine). When this occurs systemically, it can cause anaphylaxis. When it occurs in a confined area such as the skin, erythema and induration are observed within a few minutes of allergen injection. This is the principle used for detection of penicillin allergy as well as for environmental or food allergies. A positive skin reaction (≥5 mm of induration) within 15 to 20 minutes is indicative of the presence of allergen-specific IgE.

There are four subclasses of IgG: IgG1, IgG2, IgG3, and IgG4 that make up 65%, 20%, 10%, and 5% of total plasma IgG, respectively. Concentrations of the subclasses are often measured in patients with suspected primary and secondary hypogammaglobulinemia. IgG2 and IgG4 deficiencies are associated with chronic infections. IgG4 deficiencies are also associated with autoimmune disorders.

COMPLEMENT SYSTEM

The complement system consists of a group of over 30 different proteins involved in lysing and opsonizing invading pathogens as well as serving as chemotactic factors. Numbers following the letter C (e.g., C1, C2) name the various proteins of the complement system. A test for the global assessment of the complement system is the CH_{50}, the total hemolytic complement test. This test is based on the premise that complement is needed for a rabbit anti-sheep antibody to lyse sheep red blood cells. The source of the complement is the patient's serum. Each laboratory standardizes the test so normal ranges vary, but a standard curve is developed by adding titrated amounts of sera and measuring the amount of hemolysis. The hemolysis is determined with a spectrophotometer to measure the amount of hemoglobin released. The patient's serum is then tested, and the amount of serum that is needed to lyse 50% of the red blood cells is reported as the CH_{50}. This test does not provide an indication of the function of any specific complement component but is used as a screening test for any complement system defects. If a defect is found, individual complement proteins can then be evaluated by functional or immunochemical methods. Assessment of the complement system is important in patients suspected of having humoral immune deficiencies (i.e., recurrent infections).[43]

Several disease states can alter complement concentrations. Low complement concentrations are frequently found during states of acute inflammation (e.g., systemic lupus erythematosus [SLE], rheumatoid arthritis, collagen vascular disorders, poststreptococcal glomerulonephritis, and subacute bacterial endocarditis). These states of apparent low complement concentrations are generally due to high rates of complement utilization or consumption that cannot be compensated for by increased complement synthesis.[20]

Since the liver is the primary source of several components of the complement system (i.e., C2, C3, C4, factors B and D), a global decrease in complement factors occurs in severe liver failure. Inherited complement deficiencies have been described in patients with SLE, autoimmune diseases, recurrent gonococcal and meningococcal infections, membranoproliferative glomerulonephritis, and hereditary angioedema.[20]

Clinically, the complement system has been used to diagnose and treat solid organ rejection. Antibody mediated or humoral rejection is evaluated by quantifying the amount of donor MHC specific antibody present in the recipient's serum. The presence of donor-specific antibodies is correlated with evidence of antibody mediated rejection on tissue samples. This is characterized by the presence of complement split products, namely C4d, which is present after complement-dependent antibody-mediated rejection. C4d covalently binds to the allograft tissue and can be stained for on biopsy samples. Unfortunately unless biopsy findings can be correlated with a clinical finding consistent with rejection, the presence of C4d and its prognosis on long-term allograft function are unknown.

CYTOKINES

Cytokines are an important means of communication among cells of the immune system and other organ systems. Multiple cytokines with overlapping and redundant functions have been identified. Methods to detect and measure cytokines in biological samples have been developed. For nearly all the currently identified cytokines, commercial kits are available to measure endogenous and exogenously administered cytokines. The most common and preferable methods to measure cytokines are ELISAs and RIAs. ELISAs and RIAs are easy to run and measure immunoactivity but not biologic activity (Fig. 95–7). Bioassays measure biologic activity, but are cumbersome and extremely variable. Using ELISA, we are able to measure only how much cytokine was produced by the cells in the culture. An ELISPOT is an enzyme-linked assay for detecting and enumerating cytokine-producing leukocytes.[49] In contrast to conventional ELISA, ELISPOT allows the user to detect absolute numbers and frequencies of cytokine secreting leukocytes.

We are still at the very early stages of interpreting the clinical relevance of endogenous cytokine concentrations. Not only is the immune system affected by cytokines such as IL-1, IL-6, TNF-α, but other systems (skeletal, endocrine, central nervous system) are also affected. Therefore, measurement of cytokine concentrations may be important in the evaluation of other systems as well as the immune system.

Administering cytokines in clinical practice may change not only the concentration of that particular cytokine, but also the resultant concentration of other cytokines. For example, systemic administration of GM-CSF to patients not only increases concentrations of GM-CSF but also of TNF-α, IL-6, IL-8, macrophage colony-stimulating factor and erythropoietin.[50,51] Secondary endogenous cytokine release should be taken into account when considering the therapeutic effects of these agents and when monitoring cytokine concentrations.

In the future, tissue concentrations as well as blood concentrations may be measured. For example, while many centers currently measure cyclosporine concentrations to estimate the potential for immunosuppressive effects, it may be advantageous to monitor IL-2 concentrations. One of the primary actions of cyclosporine is the inhibition of IL-2 production. Furthermore, perhaps it would be beneficial to measure tissue concentrations of IL-2 in the transplanted organ to get a better estimate of the extent of immunologic suppression.

SOLUBLE RECEPTORS AND RECEPTOR ANTAGONISTS

The inflammatory response is highly regulated. The activity of cytokines, their receptors, and their antagonists are in a delicate balance. Although cytokine receptors are typically thought of as being found on the target cell, soluble cytokine receptors can modulate the activity of cytokines in at least two ways: (1) acting as antiinflammatory agents by binding cytokines with high affinity, but without biological activity[52]; (2) augmenting cytokine activity by prolonging the cytokines plasma half- life and even maintaining agonist activity on cells that do not inherently respond to the cytokine.[53] Finally, antagonists to cytokine receptors have been identified.

Tumor necrosis factor-α (TNF-α) plays a central role in the inflammatory response by both increasing the expression of adhesion molecules in the tissues and by stimulating production of pro-inflammatory cytokines (e.g., IL-2, IL-8), prostaglandins, and nitric oxide. Soluble tumor necrosis factor receptors (sTNFRs) act primarily as inhibitors of TNF by preventing TNF from binding to the membrane-bound TNFRs, or by causing the cells to shed the receptor from the surface of the cell so that it can no longer serve as a signaling molecule.[54] Both monoclonal antibodies against TNF (e.g., infliximab) and sTNFRs (e.g., etanercept) have been shown to modulate the activity of TNF and are used clinically for the treatment of autoimmune diseases.

The best characterized receptor-binding antagonist is the interleukin-1 receptor antagonist (IL-1RA). IL-1RA blocks the binding of IL-1 to its receptor by competing for the same binding site, but IL-1RA does not possess agonist activity.[55] A recombinant IL-1RA, anakinra, is used clinically for the treatment of severe rheumatoid arthritis.[56]

Our developing understanding of soluble receptors and receptor antagonists allows us to better mimic natural mechanisms for minimizing the toxicity of exogenously administered cytokines (e.g., IL-1, IL-2, TNF-α, etc.) as well as immunomodulate various diseases (e.g., solid organ transplant rejection, collagen vascular disorders, sepsis, etc.)

MODULATION OF THE IMMUNE RESPONSE

6 Modulation of the immune response through administration of pharmacological agents or with blood product components does not come without a risk gained with the benefit. Providing supplementation to the immune system, for example during periods of sepsis with recombinant activated protein C (drotrecogin alfa) provides increased levels of protein C which decrease levels of pro-inflammatory IL-6 potentially limiting the effects of the immune reaction and preventing end organ damage at the cost of bleeding for over exposure to protein C. While TNF inhibitors interfering with the immune system to halt the damage of an autoimmune disorder may suppress symptoms, it places the patient at risk for opportunistic viral infections. Many of our newer biological agents directed at a pathway in the immune system are genetically engineered from animals and humanized to increase their biological effectiveness. As a result, these agents can serve as antigens to the immune system and display variable effectiveness between and among patients over time. For example, an agent commonly used in solid organ transplantation is rabbit anti-thymocyte globulin, which is a polyclonal antibody directed against lymphocytes which given at the time of transplant or to treat rejection. Patients with previous exposure to this agent may have developed antibodies against the rabbit epitope of the drug. This results in either a decrease in the effectiveness of the drug, because it is bound by antibody or production of an immunologic reaction, commonly manifested by antibody-antigen complex deposition in the kidneys and joints producing high fevers and renal failure. Based on the very few examples presented here, one can understand why manipulation of the immune system must be carefully assessed and appropriate patient instruction given.

IMMUNOSUPPRESSION

Immunosuppression was first developed and used to allow transplantation of foreign tissues or to treat malignancies of the immune system. Today, the number of compounds and disease states in which the immune system is implicated is virtually unquantifiable. Therefore a thorough review of these drugs is beyond the scope of this chapter. These medications are usually very expensive and associated with potentially serious adverse effects. Immunosuppressants block critical steps of the immune response, and patients must be counseled on their risk of infection and the plan to monitor effectiveness of the immunosuppressant. Several key concepts and questions can be used to help clinicians discern the potential benefits and ramifications of administering any immunosuppressant. These include: (1) what is its mechanism of action, (2) what arm of the immune system does it effect, (3) when is its onset of action, (4) how was this compound derived and does it have the potential to stimulate antibody production if the patient is re-exposed, (5) is this compound's effect dose or duration related, (6) what type of infection is my patient at risk for and do I need to administer prophylactic medications, and (7) how do I monitor the biological effect of this compound?

IMMUNOPOTENTIATION

In an attempt to restore normal immune system function or to activate the immune system, immunopotentiators are often used. The best example of immunopotentiation of the immune system is the practice of immunizations. Active immunization with a vaccine or toxoid induces the host's immune system to confer protection against a pathogen (e.g., hepatitis A, hepatitis B, diphtheria toxoid, etc.). This process requires the uptake of the immunogenic epitope by antigen presenting cells followed by presentation to $CD4^+$ T lymphocytes and the subsequent development of either a cellular or humoral immune response.

In contrast to active immunization, passive immunity entails the administration of human immunoglobulin to provide short-term protection to individuals who will be or have been exposed to a pathogen. Intravenous immunoglobulin (IVIG) consists of >90% polyclonal IgG that is prepared from donated plasma. In patients with primary or secondary hypogammaglobulinemia, IVIG restores circulating IgG concentrations thus decreasing the incidence of infections in these patients. In addition to restoring IgG concentrations, IVIG can potentially immunomodulate the immune response. For example, in immune thrombocytopenic purpura, an autoantibody directed against the platelets leads to the destruction of the platelets by antibody-dependent cellular cytotoxicity. IVIG saturates the Fc receptors on phagocytic cells, thereby preventing the engulfment of autoantibody-opsonized platelets. IVIG can also

contain anti-idiotype antibodies to immunomodulate an immune response. Anti-idiotype antibodies are directed against the idiotype or hypervariable region of a native antibody. After administration of IVIG, the anti-idiotypes bind to the hypervariable region of the autoantibody and prevent the autoantibody from opsonizing circulating platelets. In addition, the anti-idiotypes directed against the autoantibody can bind to the surface immunoglobulin on the B lymphocyte producing the autoantibody that leads to the destruction of the B lymphocyte.[57]

SUMMARY

Our understanding of the immune system has dramatically increased over the last decade. An immune response encompasses dynamic events involving both immunologic cells (e.g., phagocytes, lymphocytes) and soluble mediators (e.g., complement, cytokines, antibodies). A better understanding of the normal immune response allows us to investigate the pathophysiology of diseases in which the immune response is inappropriate. All clinicians need a basic understanding of the immune system and a familiarity with parameters to monitor immune system function in order to refine the development of immunologic treatments for diseases ranging from diabetes mellitus to collagen vascular disorders to cancer.

CHAPTER 96

Systemic Lupus Erythematosus and Other Collagen-Vascular Diseases

JEFFREY C. DELAFUENTE AND KIMBERLY A. CAPPUZZO

KEY CONCEPTS

1. Systemic lupus erythematosus (SLE) is a disease that predominantly occurs in women.
2. The hallmark of SLE is the development of autoantibodies to cellular nuclear components, resulting in chronic inflammatory autoimmune disease. Symptoms and organ involvement depend on the nature of the autoantibodies.
3. SLE has a wide spectrum of symptoms and organ system involvement, making therapy highly patient specific. In addition, the signs and symptoms will fluctuate over time.
4. The wide spectrum of symptoms and organ system involvement makes pharmacotherapy difficult because therapy must be individualized based on each patient's disease activity.
5. There is a paucity of quality evidence for the treatment of SLE except for lupus nephritis.
6. Almost all classes of medications, including antiinflammatory and immunosuppressive agents, are reported to cause vasculitis in most major organ systems.

The collagen–vascular diseases are a heterogeneous group of diseases that can involve the musculoskeletal system, integument, and blood vessels. Each collagen–vascular disease has its own set of diagnostic criteria, although diagnosis can be difficult because of overlapping and nonspecific clinical presentations. The etiology of the various collagen–vascular diseases is often unknown, but the immune system usually is involved in the pathogenesis and manifestations of the disease. Therefore, pharmacotherapy usually includes antiinflammatory agents with or without immunosuppressive drugs.

Although the prevalence of other collagen–vascular diseases may be greater than that of systemic lupus erythematosus (SLE) (e.g., polymyalgia rheumatica), SLE is discussed most extensively in this chapter because it is a major collagen–vascular disease with numerous clinical manifestations, its pharmacotherapy can be complex, and a plethora of data is available on the therapy of SLE. As all the diseases discussed in this chapter have an immune-mediated pathogenesis, the therapeutic principles of SLE can be applied to other autoimmune collagen–vascular diseases. The collagen–vascular diseases discussed include systemic sclerosis, polymyositis/dermatomyositis, polymyalgia rheumatica, and drug-induced vasculitis; these were chosen because they are seen in general practice.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a fluctuating multisystem disease with a diversity of clinical presentations. Abnormal immunologic function and formation of antibodies against "self-antigens" underlie the pathogenesis of SLE.

The term *lupus erythemateux* was first used in 1851 by Cazenave, a Frenchman who described an illness in a patient with manifestations occurring in the skin. It is not surprising that SLE was first recognized as a skin disorder because cutaneous manifestations constitute one of the most common clinical features of the disease. Further descriptions by Kaposi and Osler in the late 1800s led to the concept of a multisystem disease as it became recognized that patients developed complications in other organ systems.[1]

The hallmark of SLE is the development of autoantibodies to cellular nuclear components that leads to a chronic inflammatory autoimmune disease. Recognition of SLE as an autoimmune disease of multisystemic nature led the American College of Rheumatology to develop criteria for identifying lupus patients (Table 96–1). These criteria were developed in 1971, revised in 1982, and modified slightly in 1997. The criteria do not include all the clinical manifestations of the disease and are used primarily for distinguishing SLE from other collagen–vascular diseases.[2] If 4 or more of the 11 criteria are documented at any time in a patient's medical history, the diagnosis of SLE can be made with approximately 95% specificity and 85% sensitivity.[3] Although these criteria may be helpful, diagnosis requires additional serologic, immunopathologic, and clinical evaluations.

EPIDEMIOLOGY

1. The incidence of SLE varies among ethnic groups with the annual incidence in adults ranging from 1.9 to 5.6 per 100,000 persons per year, with a prevalence of approximately 50 cases per 100,000 persons.[1,4,5] The disease occurs predominantly in women, with a reported female-to-male ratio approaching 10:1. Those afflicted with SLE are usually diagnosed between the ages of 15 and 45.[6,7] SLE is reported to be less prevalent in whites than in other ethnic groups, including blacks, Hispanics, Native Americans, and Asians.[6,7] Although the most typical SLE patient is a young adult woman, the disease can occur in people of any age or race and either gender.

ETIOLOGY

The etiology of abnormal autoantibody production and development of SLE is still unknown. Genetic, environmental, and hormonal factors all may play a role in loss of "self-tolerance"

TABLE 96-1 Revised Criteria for Classification of Systemic Lupus Erythematosus[a]

Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observations
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis–convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion or Pericarditis–documented by electrocardiogram or rub or evidence of pericardial effusion
Renal disorder	Persistent proteinuria >0.5 g/day (500 mg/day) or >3+ if quantitation not performed or Cellular casts–may be red cell, hemoglobin, granular, tubular, or mixed
Neurologic disorder	Seizures–in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance or Psychosis–in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance
Hematologic disorder	Hemolytic anemia–with reticulocytosis or Leukopenia–fewer than 4,000 cells/mm^3 (4×10^9/L) total on two or more occasions or Lymphopenia–fewer than 1,500 cells/mm^3 (1.5×10^9/L) on two or more occasions or Thrombocytopenia–fewer than 100,000 /mm^3 (100×10^9/L) in the absence of offending drugs
Immunologic disorder	Anti-DNA; antibody to native DNA in abnormal titer or Anti-Smith (Sm) antigen; presence of antibody to Sm nuclear antigen or Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of immunoglobulin (Ig)G or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
Antinuclear	An abnormal titer of antinuclear antibody by immunofluorescence or an antibody equivalent assay at any point in time in the absence of drugs known to be associated with "drug-induced lupus" syndrome

[a]The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 1982;25:1274 and Hochberg MC. Updating the American College of Rheumatology Revised Criteria for the Classification of Systemic Lupus Erythematosus. Arthritis Rheum 1997;40;1725, with permission.

and expression of disease. A popular theory is that autoimmune disease such as SLE develops in genetically susceptible individuals after exposure to a triggering agent, possibly something in the environment.[7–9]

Genetic analysis shows that at least four susceptibility genes are required for the expression of lupus in humans.[9] Familial and twin studies indicate a genetic predisposition for the development of SLE. First-degree relatives of SLE patients are about 20 times more likely to develop SLE than the general population; more than 5% of cases are familial. The concordance rate among identical twins ranges from 24% to 58%, compared with 3% to 10% for nonidentical twins.[10] Multiple genes contribute to SLE susceptibility, and at least 100 genes have been linked to SLE in humans. Evidence indicates that major histocompatibility complex genes, particularly several human leukocyte antigen genes, may be important in lupus. However, nonmajor histocompatibility complex genes, such as immunoglobulin receptor genes and mannose-binding protein genes, also may contribute to disease susceptibility.[9,10] Environmental agents that may induce or activate SLE include sunlight (i.e., ultraviolet light), drugs, chemicals such as hydrazine (found in tobacco) and aromatic amines (found in hair dyes), diet, environmental estrogens, and infection with viruses or bacteria.[9] A number of viruses have been implicated as causative agents in genetically susceptible people with significant data identifying the Epstein Barr virus as a causative agent.[11,12] Additionally, androgen may inhibit and estrogen may enhance the expression of autoimmunity, and elevated circulating prolactin levels have been associated with lupus in males and females.[9,13]

PATHOPHYSIOLOGY

2 SLE represents a clinical syndrome rather than a discrete disease with a unique pathogenesis. SLE has a large spectrum of symptoms and organ system involvement.[1] A major event in the development of SLE is excessive and abnormal autoantibody production and the formation of immune complexes. Patients may develop autoantibodies against multiple nuclear, cytoplasmic, and surface components of multiple types of cells in various organ systems in addition to soluble markers such as immunoglobulin G and coagulation factors; these autoantibodies account for the multiple-organ system involvement of the disease.[9]

Excessive autoantibody production results from hyperactive B lymphocytes. Multiple mechanisms likely lead to B-cell hyperactivity, including loss of immune self-tolerance and high antigenic load consisting of environmental and self-antigens presented to B cells by other B cells or specific antigen-presenting cells, a shift of T-helper type 1 cells to T-helper type 2 cells that further enhance B-cell antibody production, and defective B-cell suppression. Impairment in other immune regulatory processes involving T lymphocytes (suppressor T cells), cytokines (e.g., interleukins, interferon-γ, tumor necrosis factor-α, transforming growth factor-β), and natural killer cells also may be involved.[9,14]

Many autoantibodies are directed against nuclear constituents of the cell; collectively, they are called *antinuclear antibodies*. Several antinuclear antibodies are important because their presence or absence may aid in the diagnostic and clinical evaluation of patients with SLE. The SLE patient may have more than one antigen-specific antinuclear antibody in the patient's serum and tissues.[15] These are antibodies against such nuclear constituents as double-stranded, or native, DNA (dsDNA); single-stranded, or denatured, DNA (ssDNA); and RNA. Four RNA-associated antigens frequently occurring in SLE are the Smith (Sm) antigen, the small nuclear ribonucleoprotein (snRNP), the Ro (SS-A) antigen, and the La (SS-B) antigen.[12,16] Histone, a basic component of chromatin and nucleosomes, is another important nuclear component against which antinuclear antibodies are formed in lupus patients. Antibodies to dsDNA are highly specific for SLE and are present in 70% to 80% of patients.[12] Antibodies also may be directed against the phospholipid moiety of the prothrombin

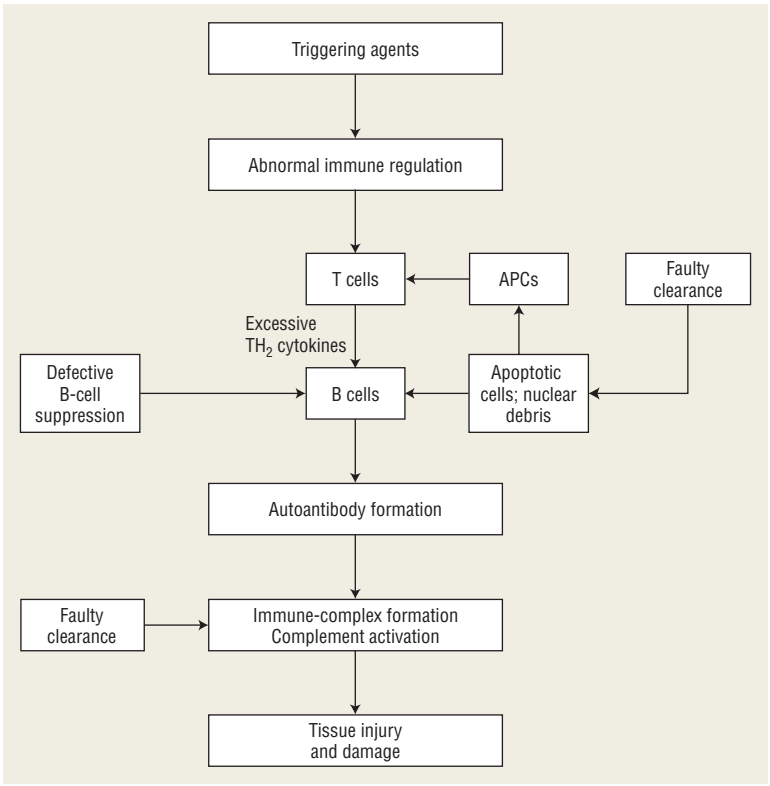

FIGURE 96-1. Pathogenesis of systemic lupus erythematosus (SLE). Environmental factors, such as infectious organisms, drugs, and chemicals, serve as triggering agents in genetically and hormonally susceptible individuals to induce a state of immune dysregulation. These abnormal immune responses lead to hyperactive T-helper type 2 lymphocyte and B-lymphocyte function. Suppressor T-lymphocyte function, cytokine production, faulty clearance mechanisms, and other immune regulatory mechanisms also are abnormal and fail to downregulate autoantibody formation from hyperactive B lymphocytes. The autoantibodies formed from this immune dysregulation become pathogenic, form immune complexes, and activate complement that leads to damage of host tissue. (APCs, antigen-presenting cells; TH_2, T-helper type 2.)

activator complex (lupus anticoagulant) and against cardiolipin. The lupus anticoagulant and anticardiolipin antibodies constitute the two main types in a group of autoantibodies called *antiphospholipid antibodies*.

These autoantibodies often are present many years before the diagnosis of SLE.[17] The appearance of these autoantibodies follows a predictable pattern, with accumulation of specific autoantibodies before the onset of clinical illness. For example, antinuclear, anti-La, anti-Ro, and antiphospholipid antibodies often precede the onset of SLE by many years, whereas anti-Sm and anti-snRNP antibodies appear only months before diagnosis, usually when clinical symptoms begin to manifest.

Immune dysregulation leading to B-cell hyperactivity and subsequent production of pathogenic autoantibodies, coupled with defective clearance of apoptotic cells, followed by immune-complex formation, complement activation, and defective clearance of immune complexes all lead to inflammatory reactions that ultimately result in tissue injury and damage. Figure 96–1 is an overview of the pathogenesis of SLE.[9]

CLINICAL PRESENTATION

3 As mentioned previously, SLE is a multisystem disease. Below (see Clinical Presentation of Systemic Lupus Erythematosus) are many of the signs and symptoms and incidences for patients with SLE.[18] Although certain of these may be more common than others, each patient presents differently, and the course of the disease is highly unpredictable. Furthermore, SLE is not static, and most patients have fluctuations or flare-ups during the course of the disease.

Nonspecific signs and symptoms such as fatigue, fever, anorexia, and weight loss are seen frequently for patients with active disease. Musculoskeletal involvement (e.g., arthralgia, myalgia, and arthritis) is very common in SLE, with fever, malaise, or arthralgia frequently the chief complaint on initial presentation of the disease.[18] All major and minor joints may be affected, and the pattern of arthritis is often recurrent and of short duration, presenting mainly as joint stiffness, pain, and sometimes inflammation. Objective evidence of musculoskeletal disease often is missing, although a few patients may present with deforming arthritis or subcutaneous nodules.

Manifestations in the skin are very common in lupus. The most well known of these is the butterfly rash, which occurs over the bridge of the nose and the malar eminences and is present in 50% of patients at some time during the disease.[18] The classic butterfly rash often is observed after sun exposure. In fact, photosensitivity is common to many SLE patients who present with cutaneous manifestations. Skin lesions characteristic of discoid lupus occur in up to 20% of patients with SLE and may occur without other clinical or serologic evidence of lupus.[18] Some individuals develop *subacute cutaneous lupus erythematosus* on exposure to sunlight.[18] Other cutaneous manifestations include vasculitis (which may be ulcerative), oral ulcers, Raynaud's phenomenon, and alopecia.[18]

Another common source of symptomatology in SLE is the pulmonary system, with manifestations such as pleurisy, coughing, and dyspnea. Pleurisy may present as pleuritic pain, a pleural rub, or a pleural effusion that usually is exudative in nature. Lupus pneumonitis may present acutely with fever, dyspnea, tachypnea, cough, rale, and patchy infiltrates or chronically with interstitial fibrosis. Pulmonary hypertension associated with SLE is more common than previously thought, which is likely a result of asymptomatic increases in pulmonary artery pressures being more common than symptomatic increases. Patients with SLE-associated pulmonary hypertension have a poor prognosis. Pulmonary embolism also should be ruled out for any SLE patient presenting with pleuritic chest pain and dyspnea.

Cardiac manifestations of SLE often present as pericarditis, myocarditis, electrocardiographic changes, or valvular heart disease, including the classic cardiac lesion of Libman-Sacks endocarditis (nonbacterial verrucous endocarditis).[19] Coronary artery disease (CAD) is being seen in SLE with increasing frequency as the life expectancy of SLE patients increases.[20] The development of heart

disease in these patients is probably multifactorial, and traditional CAD risk factors are common for patients with SLE.

CLINICAL PRESENTATION OF SYSTEMIC LUPUS ERYTHEMATOSUS

Sign and/or Symptom	Incidence (%)
Musculoskeletal	
Arthritis and arthralgia	53 to 95
Constitutional	
Fatigue	81
Fever	41 to 86
Weight loss	31 to 71
Mucocutaneous	55 to 85
Butterfly rash	10 to 61
Photosensitivity	11 to 45
Raynaud's phenomenon	10 to 44
Discoid lesions	9 to 29
Central nervous system	13 to 59
Psychosis	5 to 37
Seizures	6 to 26
Pulmonary	
Pleuritis	31 to 57
Pleural effusion	12 to 40
Cardiovascular	
Pericarditis	2 to 45
Myocarditis	3 to 40
Heart murmur	1 to 44
Hypertension	23 to 46
Renal	13 to 65
Gastrointestinal	
Nausea	7 to 53
Abdominal pain	8 to 34
Bowel hemorrhage (vasculitis)	1 to 6
Hematologic	
Anemia	30 to 78
Leukopenia	35 to 66
Thrombocytopenia	7 to 30
Lymphadenopathy	10 to 59

Corticosteroid therapy and immunosuppressive therapy are also believed to be contributing factors in the development of these cardiac risk factors.[19] Although hypertension, obesity, and hyperlipidemia are common for SLE patients, these traditional risk factors do not account for the strikingly high cardiovascular event rate found in some recent studies.[21] Other SLE-related risk factors highlight the importance of autoimmunity and inflammation in the pathogenesis of accelerated atherosclerotic cardiovascular disease.[21,22] Additionally, two studies reported that long-term corticosteroid therapy was not associated with a significantly increased risk of accelerated atherosclerosis.[23,24] In fact, one of the studies[23] found that patients with higher mean daily doses of prednisone and more frequent use of other common therapies for SLE exhibited less plaque formation, which suggests that more aggressive control of disease activity actually may help to prevent CAD.[22,23]

CLINICAL CONTROVERSY

Some research suggests that long-term corticosteroid therapy is responsible for the increased incidence of coronary heart disease, whereas other data suggest that it has no effect on atherosclerosis.

Neuropsychiatric manifestations of SLE may present in many ways, including headaches, psychosis, depression, anxiety, seizure, stroke, peripheral neuropathy, cognitive impairment, and others.[4] Cognitive dysfunction is observed in 12% to 87% of patients with SLE. Depression and anxiety are common among SLE patients, but it is unclear if they are direct manifestations of central nervous system (CNS) involvement or secondary to the distress of living with a chronic illness.

Symptoms associated with gastrointestinal manifestations often are nonspecific for lupus and include dyspepsia, abdominal pain, nausea, and difficulty swallowing. Mesenteric vasculitis and venous occlusion owing to thrombosis may be problematic if not diagnosed and treated promptly. Hepatitis and pancreatitis also may be present and may be secondary to drugs used to treat SLE or the disease itself.

Anemia is found in many patients with SLE. It is usually an anemia of chronic inflammation, with a mild normochromic, normocytic smear and low serum iron concentration but adequate iron stores. Some patients may develop a hemolytic anemia with a positive Coombs test.[25] Leukopenia, usually mild, is a common finding for SLE patients. Both granulocytes and lymphocytes may be affected, but granulocytopenia is infrequent.[25] Thrombocytopenia may occur in SLE, often during disease exacerbation, but it is usually mild and does not increase bleeding tendency.[25] Another significant finding associated with SLE is the presence of antiphospholipid antibodies such as the lupus anticoagulant and anticardiolipin antibodies. Although the lupus anticoagulant is directed against the prothrombin activator complex, which implies potential bleeding complications, this is not the case. In fact, the presence of lupus anticoagulant, anticardiolipin, or other antiphospholipid antibodies may be associated with thrombosis, neurologic disease, thrombocytopenia, and fetal loss.[26]

Clinical evidence of renal involvement, such as a rising serum creatinine or proteinuria level, generally is associated with a poorer outcome compared with patients without renal involvement. Progression to end-stage renal disease is a major cause of morbidity and mortality in SLE. However, the extent and course of renal disease are quite variable, and many lupus nephritis patients do very well. The World Health Organization has classified lupus nephritis on the basis of histologic characteristics observed following renal biopsy. A revision of this system by the International Society of Nephrology and Renal Pathology Society recommends modifying the lupus nephritis classifications as minimal mesangial (class I), mesangial proliferative (class II), focal (class III), diffuse (class IV), membranous (class V), and advanced sclerosing (class VI).[27] Many patients progress from one form of nephritis to another during the course of the disease. Predictors of poorer outcome in lupus nephritis include African-American race, anemia, azotemia, poor initial response to immunosuppressive drugs, and flares of worsening renal function.[1]

DIAGNOSIS

As mentioned earlier, the diagnostic criteria listed in Table 96–1 should not be the primary means for diagnosing SLE, although many of the criteria may be valuable in the diagnostic process.

TABLE 96-2 Antinuclear Antibody Test: Patterns, Antigens, and Specificities

Pattern	Antigen	Disease
Peripheral	dsDNA	SLE
Speckled	Acidic nuclear protein	Rheumatoid arthritis
	Ribonucleoprotein	SLE
	Extractable nuclear antigen	Scleroderma; mixed connective tissue disease
Homogeneous	dsDNA, ssDNA	Rheumatoid arthritis
	Histones	SLE; drug-induced lupus
Nucleolar	Nucleolar RNA	Progressive systemic sclerosis

ds, double-stranded; SLE, systemic lupus erythematosus; ss, single-stranded.

Epidemiologic characteristics, clinical signs and symptoms, and common laboratory abnormalities are all used in the diagnosis of SLE.

Once the disease is suspected, serologic tests may be helpful in making the diagnosis. A serologic test used extensively to aid in the diagnosis of SLE is the fluorescent antinuclear antibody (ANA) test. Nearly all SLE patients are ANA positive, but other diseases also can be associated with a positive test (Table 96–2). However, in other diseases, many of the positive ANA tests are of a lower titer. The pattern of immunofluorescence of the ANA test also may be of diagnostic value (Table 96–2), with a peripheral (also called *rim*) pattern being specific for SLE. Detecting antibodies to specific nuclear constituents also may be useful diagnostically. Antibodies to native DNA (dsDNA) and to Sm antigen are quite specific for and are considered diagnostic of SLE.[9,28,29]

PROGNOSIS

In earlier years, SLE was associated with a poor prognosis. For example, three decades ago 5-year survival was approximately 83% and 10-year survival was approximately 76%.[4] Today, as a result of improved treatment and improved diagnostic techniques that allow earlier diagnosis, the approximate 5-year survival rate is 96%, and the 15-year survival rate is 76%.[30] The natural course of SLE has changed dramatically not only because of improved therapies but also because of improvement in ability to manage patients with kidney disease (e.g., dialysis), infection, and CAD. However, complications of immunosuppressive treatment, CAD, and infection are still among the leading causes of death among SLE patients.[30]

TREATMENT

Systemic Lupus Erythematosus

4 Desired treatment outcomes for the patient with SLE are two-fold: (1) management of symptoms and induction of remission during times of disease flare and (2) maintenance of remission for as long as possible between disease flares. Figure 96–2 outlines an approach to the management of the patient with SLE. Because of the variability in clinical presentation of disease, treatment will vary accordingly and should be highly individualized. Optimal care of the patient with SLE will include education and support services in addition to the nonpharmacologic and pharmacologic

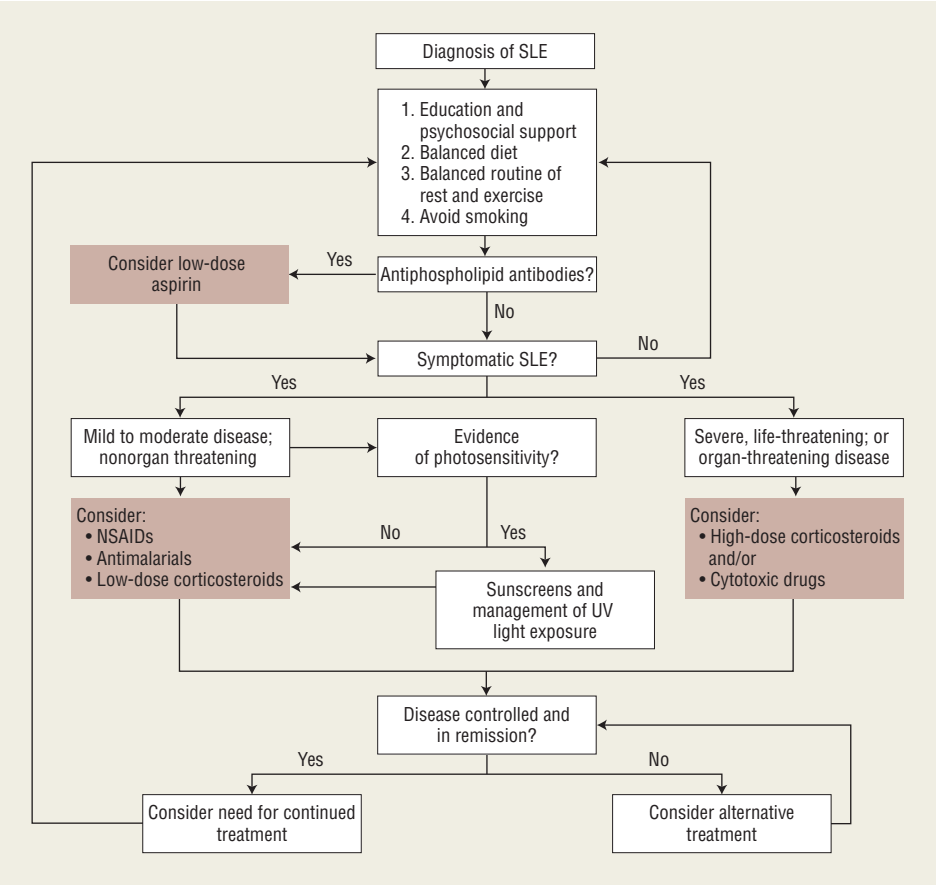

FIGURE 96-2. General approach to the management of SLE (NSAIDs, nonsteroidal antiinflammatory drugs; UV, ultraviolet).

treatments discussed below. Numerous lupus organizations exist throughout the world and can be located by contacting the Lupus Foundation of America (*http://www.lupus.org*), the Arthritis Foundation (*http://www.arthritis.org*), and Lupus Canada (*http://www.lupuscanada.org*).

NONPHARMACOLOGIC THERAPY

Several nonpharmacologic measures can be employed to manage symptoms and help maintain remission. Fatigue is a common symptom for patients with lupus. A balanced routine of rest and exercise, while avoiding overexertion, is essential in managing fatigue.[31] Avoidance of smoking may be particularly important because hydrazines in tobacco smoke may be an environmental trigger of lupus and likely contribute to accelerated CAD.[9] Smoking also has been associated with increased disease activity for SLE patients.[32] No specific dietary measures are known to clearly affect the clinical course of lupus. Many patients with SLE will need to limit exposure to sunlight and use sunscreens to block the possible exacerbating effects of ultraviolet light.[31] The amount of sunlight exposure limitation should be individualized.

PHARMACOLOGIC THERAPY

5 Drug therapy for SLE is often designed to suppress the immune response and inflammation. Except for lupus nephritis, large controlled clinical trials comparing treatment options for SLE are needed. Table 96–3 lists common agents and doses used to control SLE. In general, the choice of drug therapy depends on the extent and severity of disease. Table 96–4 describes select monitoring parameters and adverse events for many of the drugs used to treat collagen–vascular diseases.

TABLE 96-3 Drug Treatment of Systemic Lupus Erythematosus

Drug Class	Drug and Dose	Indication
NSAID	Various agents Antiinflammatory dose	Mild disease: fever, arthritis, skin rash, serositis
Antimalarial	Hydroxychloroquine 200–400 mg po daily Chloroquine 250–500 mg po daily	Mild disease: arthritis, skin rash, serositis
Corticosteroid	Prednisone 1–2 mg/kg/day po (or equivalent) <1 mg/kg/day (or equivalent)	Initial control of severe disease Control of mild disease or maintenance after disease suppression with higher doses
	Methylprednisolone 500–1,000 mg IV daily for 3–6 days	Life-threatening disease
Cytotoxic	Cyclophosphamide 0.5–1 g/m^2 IV monthly for 6 months; then every 3 months for 2 years or for 1 year after remission Azathioprine 1–3 mg/kg po daily Cyclophosphamide 1–3 mg/kg po daily Mycophenolate mofetil 1–3 g po daily	Most commonly used in severe lupus nephritis; may be necessary for other severe disease manifestations

IV, intravenously; NSAID, nonsteroidal antiinflammatory drugs; po, orally.

Nonsteroidal Antiinflammatory Drugs

As discussed earlier, signs and symptoms such as fever, arthritis, and serositis are among the most common for patients with active disease. Therefore, for many patients with mild disease, initial

TABLE 96-4 Monitoring Adverse Effects of Drugs Commonly Used in Systemic Lupus Erythematosus

			Monitoring	
Drug	**Toxicities to Monitor**	**Baseline Evaluation**	**System Review**	**Laboratory**
Salicylates, NSAIDs	Gastrointestinal bleeding, hepatic toxicity, renal toxicity, hypertension	CBC, creatinine, urinalysis, AST, ALT	Dark/black stool, dyspepsia, nausea/vomiting, abdominal pain, shortness of breath, edema	CBC yearly, creatinine yearly
Corticosteroids	Hypertension, hyperglycemia, hyperlipidemia, hypokalemia, osteoporosis, avascular necrosis, cataract, weight gain, infections, fluid retention	Blood pressure, bone densitometry, glucose, potassium, cholesterol, (HDL, LDL), triglycerides	Polyuria, polydipsia, edema, shortness of breath, blood pressure, visual changes, bone pain	Glucose every 3–6 months, total cholesterol yearly, bone densitometry yearly to assess osteoporosis
Hydroxychloroquine	Macular damage	None unless patient is older than 40 years of age or has previous eye disease	Visual changes	Funduscopic and visual fields every 6–12 months
Azathioprine	Myelosuppression, hepatotoxicity, lymphoproliferative disorders	CBC, platelet count, creatinine, AST or ALT	Symptoms of myelosuppression	CBC and platelet count every 1–2 weeks with changes in dose (every 1–3 months thereafter), AST yearly, Pap test at regular intervals
Cyclophosphamide	Myelosuppression, myeloproliferative disorders, malignancy, immunosuppression, hemorrhagic cystitis, secondary infertility	CBC and differential and platelet count, urinalysis	Symptoms of myelosuppression, hematuria, infertility	CBC and urinalysis monthly, urine cytology and Pap test yearly for life
Mycophenolate mofetil	Myelosuppression, hepatotoxicity, lymphoproliferative disorders, malignancy	CBC, hepatic function tests, renal function tests	Symptoms of myelosuppression, diarrhea, nausea/vomiting, dyspepsia, abdominal pain, dark/black stool or blood in stool	CBC weekly during first month, twice monthly during the second and third months, then monthly through the first year

ALT, alanine transaminase; AST, aspartate transaminase; CBC, complete blood count; HDL, high-density lipoprotein; LDL, low-density lipoprotein; NSAIDs, nonsteroidal antiinflammatory drugs; Pap, papanicolaou.

Modified from American College of Rheumatology Ad Hoc Committee on Systemic Lupus Erythematosus Guidelines. Guidelines for referral and management of systemic lupus erythematosus in adults. Arthritis Rheum 1999;42:1790, with permission.

treatment with a nonsteroidal antiinflammatory drug (NSAID) is a logical choice. The choice of NSAIDs in SLE is empirical. The dose used should be adequate to provide antiinflammatory effects, although low-dose aspirin may be useful in the management of patients with antiphospholipid syndrome.[33]

Nonselective cyclooxygenase NSAIDs significantly increase the risk of gastric irritation and peptic ulceration. Coprescribing with a gastroprotective agent such as a proton pump inhibitor may be beneficial. Patients with SLE taking NSAIDs may experience a decline in renal function because of drug effects and not the underlying disease. NSAIDs can decrease renal blood flow and glomerular filtration rates and should be used cautiously for patients with nephritis. Awareness of this adverse effect is important because declining renal function may be attributed mistakenly to progression of lupus nephritis. Patients with SLE have a higher incidence of hepatotoxicity than do other patients taking traditional NSAIDs. The use of NSAIDs is also associated with aseptic meningitis in SLE patients.[34]

Antimalarial Drugs

Antimalarial agents such as chloroquine and hydroxychloroquine have been used successfully in the management of discoid lupus and SLE. A few controlled trials provide evidence for the role of antimalarial therapy in controlling disease exacerbations and as steroid-sparing agents.[35] In general, the manifestations of SLE that can be managed with antimalarials are cutaneous manifestations, arthralgia, fatigue, and fever.[1,31] Because these drugs are not effective immediately, they are best used in long-term management. Response to chloroquine occurs within 1 to 3 months, whereas the maximal effect of hydroxychloroquine may not occur for 6 to 12 months.[36] Hydroxychloroquine is probably safer than chloroquine and is considered the antimalarial of first choice.

The mechanism of action of the antimalarial drugs is uncertain. It has been proposed that antimalarials interfere with T-lymphocyte activation.[36] Other effects of antimalarials that may benefit patients with SLE include inhibition of cytokines, decreased sensitivity to ultraviolet light, antiinflammatory activity, antiplatelet effects, and antihyperlipidemic activity.[22,36]

Dosage and duration of therapy depend on patient response, tolerance of side effects, and development of retinal toxicity, which is a potentially irreversible adverse reaction associated with long-term therapy, especially with chloroquine. Current recommended doses of antimalarials in SLE are hydroxychloroquine 200 to 400 mg/day and chloroquine 250 to 500 mg/day. After 1 or 2 years of treatment, gradual tapering of dosage can be attempted. Some patients may require only 1 or 2 tablets per week to suppress cutaneous manifestations.[36]

Side effects of these drugs include CNS effects (e.g., headache, nervousness, insomnia, and others), rashes, dermatitis, pigmentary changes of the skin and hair, gastrointestinal disturbance (e.g., nausea), and reversible ocular toxicities such as cycloplegia and corneal deposits. Potentially serious retinal toxicity is uncommon when the currently recommended doses are used and is least common with hydroxychloroquine.[36] However, because of the possibility of permanent damage associated with the retinopathy, an ophthalmologic evaluation should be done at baseline and every 3 months when chloroquine is used and every 12 months when hydroxychloroquine is used.[36]

Corticosteroids

Corticosteroid therapy is commonplace in therapeutic regimens for SLE. Although evidence for improved survival with corticosteroid therapy is inadequate, these agents are known to suppress the clinical expression of disease and are considered by many to be a major factor in the improved prognosis in recent years. Most controlled trials of corticosteroid therapy have been conducted for patients with severe lupus nephritis, but evidence suggests that corticosteroids are also effective in the management of severe cases of CNS disease, pneumonitis, myositis, vasculitis, thrombocytopenia, and other clinical manifestations.[37]

A patient with the diagnosis of SLE does not automatically require corticosteroid therapy. Mild disease with such manifestations as fever, arthralgia, pleuritis, or skin manifestations may respond adequately to NSAIDs or antimalarials, but patients with clinical manifestations that are more serious or unresponsive to other drugs usually require corticosteroids.

The goal of treatment with corticosteroids in SLE is to suppress and maintain suppression of active disease with the lowest dose possible. For patients with mild disease, low-dose therapy (prednisone 10 to 20 mg/day) is adequate,[29,37] but for patients with more severe disease (severe hemolytic anemia or cardiac involvement), higher doses, such as prednisone 1 to 2 mg/kg daily, may be required. Once adequate suppression of disease is achieved, the dose should be tapered to the minimum amount required for continued disease suppression. When analyzing the need to treat with corticosteroids, the clinician should consider other conditions that may increase the risk of corticosteroid therapy, such as infection, hypertension, atherosclerotic disease, diabetes, obesity, osteoporosis, and psychiatric disease.

Steroid pulse therapy is the administration of short-term, high-dose intravenous corticosteroids with the goal of inducing remission in SLE patients with serious, life-threatening disease, such as severe active nephritis, CNS involvement, or hemolytic disease. A standard pulse regimen consists of intravenous methylprednisolone 500 to 1,000 mg for 3 to 6 consecutive days. Pulse therapy usually is followed by high-dose prednisone (1 to 1.5 mg/kg per day) therapy that is tapered to low-dose maintenance therapy.[37] Potential advantages of pulse therapy over high-dose oral steroids include a quicker response and avoidance of side effects associated with the longer duration of therapy required with oral steroids. Although generally well tolerated, methylprednisolone pulse therapy may result in significant adverse effects, including infection, gastrointestinal disturbances, rapid increases in blood pressure, arrhythmias, seizures, and sudden death. Furthermore, there are insufficient data from controlled clinical trials to clearly define the role of pulse steroids in the management of SLE. Thus pulse therapy represents an alternative mode of treatment for patients with life-threatening disease or disease unresponsive to other pharmacotherapy.

Cytotoxic Drugs

A considerable amount of literature exists describing the use of cytotoxic and immunosuppressive drugs in SLE, although few of these are reports of controlled clinical trials. Included in this category are the alkylating agent cyclophosphamide and the antimetabolite azathioprine. These agents, usually used in combination with corticosteroids, have been the mainstays of immunosuppressive therapy. Although both are known to suppress and stabilize extrarenal disease activity, much of the evaluation of these agents has focused on lupus nephritis, a major factor associated with morbidity and mortality in SLE.

Evidence supporting the use of cyclophosphamide in lupus nephritis has been collected over the last several decades. Controlled clinical trials have shown that cyclophosphamide improves long-term outcomes in lupus nephritis.[1,38,39] Based on controlled trials, combination prednisone and cyclophosphamide has become standard treatment for focal and diffuse proliferative lupus nephritis (World Health Organization classes III/IV) and is superior to prednisone alone.[38] No studies have evaluated cyclophosphamide in earlier stages of nephritis (World Health Organization classes II/III), and therefore, corticosteroids remain the treatment of choice for the initial treatment of nephritis.[40] Pulse intravenous cyclophos-

phamide plus prednisone is more effective at slowing progression to end-stage renal disease than either prednisone alone or prednisone plus azathioprine.[41] Cyclophosphamide plus corticosteroids, the current standard of care, decreases the risk of developing end-stage renal failure requiring dialysis and renal transplantation.[42,43] Intermittent pulse administration of intravenous cyclophosphamide is preferred over daily oral therapies because of reduced adverse effects. However, pulse cyclophosphamide plus prednisone is not always effective.

When used in combination with corticosteroids, cyclophosphamide is dosed at 1 to 3 mg/kg for oral therapy and 0.5 to 1 g/m^2 of body surface area for intravenous therapy. The most common route of cyclophosphamide administration is intravenous, although there is little evidence that this is better than oral administration.[44] Likewise, there is no evidence to suggest the optimal duration of treatment. Based on empirical experience, cyclophosphamide generally is dosed monthly for 6 to 7 months and then every 3 months for a period of either 2 years or for 1 year after the nephritis is in remission.[1,38,39] Of course, cyclophosphamide therapy is not without risk. Serious toxic effects include suppression of hematopoiesis, opportunistic infections, bladder complications (e.g., hemorrhagic cystitis and cancer), sterility, and teratogenesis. White blood cell counts must be monitored during cyclophosphamide therapy, and if the nadir is less than 1,500 cells/mm^3 (1.5×10^9/L), the dose must be adjusted to keep the white cell count above 1,500 cells/mm^3 (1.5×10^9/L).

Azathioprine can be used as a "steroid-sparing" agent, allowing for the reduction of corticosteroid doses.[29,42] Azathioprine has not been studied as extensively as cyclophosphamide for lupus nephritis. Data do not support the use of azathioprine as a part of an induction regimen; however, long-term maintenance azathioprine therapy may prevent renal flares after successful induction with cyclophosphamide.[39,42] Azathioprine is given orally in doses of 1 to 3 mg/kg per day, often in combination with corticosteroids for severe disease. Azathioprine generally is less toxic than cyclophosphamide, but adverse reactions may be serious and include myelosuppression, opportunistic infections including herpes zoster, cancer, hepatotoxicity, and ovarian failure.

Cyclophosphamide often is administered intravenously in intermittent pulse doses to minimize toxicity. To decrease the risk of bladder toxicity, patients should be well hydrated with oral or intravenous fluids, and urinary output should be monitored. Mesna may be used to prevent hemorrhagic cystitis. Mesna is dosed at 20% of the total cyclophosphamide dose and is administered immediately before cyclophosphamide therapy and 3, 6, and 9 hours after therapy.[45] Cyclophosphamide may be of benefit to some patients with other serious, refractory manifestations of lupus, including neurologic manifestations.[46]

Because of the adverse effects of cyclophosphamide, other approaches to treating lupus nephritis have been attempted. Mycophenolate mofetil is an immunosuppressive agent that is effective treatment for severe renal and nonrenal lupus refractory to conventional cytotoxic agents.[39,47] Mycophenolate mofetil has been investigated as an alternative to cyclophosphamide for induction of remission. In an open-label trial, mycophenolate mofetil was more effective than standard cyclophosphamide therapy, achieving a higher rate of complete and partial remissions.[43] Prednisone was used in both treatment arms. Mycophenolate mofetil was also better tolerated. In this study, mycophenolate mofetil was initially dosed at 500 mg twice daily and was increased to 750 mg twice daily after 2 weeks; the dose continued to be increased weekly to a maximum of 1,000 mg three times daily. A larger study with longer follow-up is needed before any definitive conclusion can be drawn about the superiority of mycophenolate mofetil as induction therapy. Patients with the most severe forms of lupus nephritis should receive the standard boluses of intravenous cyclophosphamide plus corticosteroid therapy, but mycophenolate mofetil plus corticosteroid therapy may be a reasonable option for patients with mild to moderate nephritis and good renal function.[48]

CLINICAL CONTROVERSY

The use of intravenous cyclophosphamide for lupus nephritis as the standard of care is being questioned as newer data suggest that mycophenolate mofetil may be just as effective for induction and maintenance therapy.

Alternatives to cyclophosphamide for maintenance therapy also have been studied. Following induction therapy with the standard cyclophosphamide protocol, patients were assigned to either intravenous cyclophosphamide (0.5 to 1 g/m^2 every 3 months), oral azathioprine (1 to 3 mg/kg per day) or oral mycophenolate mofetil (500 to 3,000 mg per day) with dose titrations. All groups received prednisone.[49] This open-label study showed that standard cyclophosphamide induction therapy followed by mycophenolate mofetil or azathioprine was more effective and better tolerated than standard cyclophosphamide bolus therapy. Although these data need to be interpreted cautiously because of study design limitations, azathioprine and mycophenolate mofetil are good options for maintenance therapy in lupus nephritis.[50]

Cytotoxic therapy is useful in combination with corticosteroids, allowing for lower steroid doses and improved efficacy compared with steroids alone. However, cytotoxic therapy must be monitored closely for adverse effects, and maximum response may take 6 months or longer for some patients. Monitoring for adverse events, such as infection, myelosuppression, and long-term malignancies is essential.

ALTERNATIVE AND EXPERIMENTAL TREATMENTS

As the pathogenesis of SLE continues to be elucidated, new and promising treatments are being developed. Many new therapeutic approaches are being studied in human clinical trials. Table 96–5 lists some agents currently available as well as new therapeutic agents in phase I, II, and III trials.[47,51]

SPECIAL POPULATIONS

Pregnancy

Pregnancy in SLE patients is associated with exacerbation of disease during pregnancy, exacerbation during the early postpartum

TABLE 96-5 Selected Experimental Agents for SLE

Treatment	Possible Mechanism of Action
Abatacept	Blocks interaction between T and B cells
Cyclosporine	Immunosuppressive
DHEA	Weak androgen; antiinflammatory
Eculizumab	Anticomplement (C_5)
Efalizumab	Anti-LFA-1 (T-cell adhesion molecule)
Epratuzumab	B-cell depletion
Infliximab	Tumor necrosis factor inhibitor
Rituximab	B-cell depletion
Sirolimus	Immunosuppression
Tacrolimus	Immunosuppression

DHEA, dehydroepiandrosterone; LFA-1, lymphocyte function antigen-1.

period, a greater incidence of spontaneous abortion, and a greater chance of developing preeclampsia or pregnancy-induced hypertension (particularly for patients with nephritis).

Exacerbation of lupus during pregnancy seems to be less likely if the disease is in remission at conception.[52,53] Disease exacerbations can be managed aggressively with corticosteroids, if needed, with little concern about harm to the fetus.[53] The decision to use other classes of drug therapy to control disease exacerbation should be highly individualized, although hydroxychloroquine is safe during pregnancy.[53,54] In fact, it may be safer to continue hydroxychloroquine during pregnancy than to discontinue it.[53] The decision to use cytotoxic drugs during pregnancy should be made with extreme caution because of potential harmful effects (e.g., teratogenesis, fetal loss) to the fetus.[55] Cyclosporine, methotrexate, and mycophenolate mofetil are contraindicated in pregnancy, but azathioprine can be used.[53] NSAIDs are generally safe in pregnancy but should be discontinued during the last weeks of pregnancy due to risk of premature closure of the ductus arteriosus.

Antiphospholipid antibodies may be associated with a greater likelihood of spontaneous abortion.[52,53] Corticosteroids, intravenous immunoglobulin, aspirin, and heparin, alone and in various combinations, have been used to try to improve fetal outcome.[29] Fetal survival increases with all these therapies, but there is some controversy about their use alone or in combination.[53,56] The optimal treatment regimen for pregnant patients with antiphospholipid antibodies is yet to be determined, although it has been recommended that women with antiphospholipid antibodies and no prior fetal losses should receive low-dose daily aspirin. High-risk women with a history of recurrent fetal loss should be treated with low-dose subcutaneous heparin with or without aspirin.[52,53] Low-molecular-weight heparin may be an effective alternative to low-dose heparin in the treatment of antiphospholipid syndrome-related pregnancy loss.

Although there is an increased chance of a high-risk pregnancy in women with SLE, appropriate planning and disease management will result in a high likelihood of a successful pregnancy and a healthy child.

Contraception

Estrogen-containing oral contraceptives have been avoided for women with SLE because of the link between estrogens and disease activity. Uncontrolled trials suggest that oral contraceptives exacerbate SLE, but this issue was only recently rigorously examined. There are good reasons to prescribe oral contraceptives in SLE: (1) outcomes of pregnancy are better when pregnancies are planned and conception occurs during disease remission, (2) women with very active disease or receiving teratogenic medications should use a very reliable method of birth control, and (3) estrogen-containing oral contraceptives may have a beneficial effect counteracting glucocorticoid-induced osteoporosis.[57]

The use of a combined oral contraceptive (ethinyl estradiol plus levonorgestrel), a progestin-only contraceptive (levonorgestrel), and an intrauterine device were compared for women with SLE.[58] This 12-month study showed comparable rates of disease flares and no clinically significant differences among all three groups during the trial. A placebo-controlled trial of ethinyl estradiol plus norethindrone also showed no difference in disease activity between the two groups over 12 months.[59] Neither of these two trials studied combined oral contraceptives in severe active SLE, leaving the issue of oral contraceptives for these patients unanswered. Because of the risk of thrombotic events for estrogen-treated women and the risk of thrombosis in SLE, antiphospholipid antibodies should be measured before oral contraceptives are started, and oral contraceptives should probably be avoided if these antibodies are present.[57]

Antiphospholipid Syndrome and Thrombosis

As mentioned earlier, the presence of antiphospholipid antibodies may result in several clinical manifestations, including thrombosis.[26] There is no agreement on prophylaxis of patients with antiphospholipid antibodies without a history of thromboembolism.[56] For such patients, low-dose aspirin (81 to 325 mg/day) may be used prophylactically, although efficacy is controversial.[56] Patients with an acute thrombotic event should receive standard treatment with anticoagulants (e.g., heparin). Continued treatment with warfarin to prevent recurrence may require an international normalized ratio of 3 or greater for patients with antiphospholipid syndrome and recurrent thrombotic events.[29,56] However, there is no consensus on the intensity of anticoagulation or duration of secondary prophylaxis, but as recurrence is common, patients usually are treated with oral anticoagulants indefinitely.[29]

CLINICAL CONTROVERSY

The optimal dose of aspirin and the intensity of anticoagulation therapy have not been well established, and clinicians will use various strategies for prevention of thrombosis in the presence of antiphospholipid antibodies.

Drug-Induced Lupus

Up to 10% of SLE cases may be drug-induced.[60] More than 80 drugs have been implicated as causing drug-induced lupus (DIL), although the incidence for most of these drugs is low.[60,61] Procainamide and hydralazine are associated most commonly with DIL (Table 96–6). A consensus on diagnostic criteria for DIL does not exist. To meet criteria for DIL, a patient should have exposure to a suspected drug, no prior history of idiopathic SLE prior to the use of the drug, development of ANAs (usually antihistone antibodies) and at least one clinical feature of SLE, and

TABLE 96-6 Medications Implicated in Drug-Induced Lupus[a]

Acebutolol	Interleukin 2	Pindolol
Amiodarone	**Isoniazid**	Primidone
Antitumor necrosis factor therapies	Labetalol	**Procainamide**
Atenolol	Lisinopril	Propranolol
Captopril	Lithium	Propylthiouracil
Carbamazepine	Lovastatin	**Quinidine**
Chlorpromazine	Mephenytoin	Reserpine
Ciprofloxacin	Methimazole	Simvastatin
Clobazam	**Methyldopa**	Streptomycin
Clonidine	Metoprolol	Sulfasalazine
Clozapine	**Minocycline**	Tetracycline
Diltiazem	Nifedipine	Thiazide diuretics
Ethosuximide	Oral contraceptives	Ticlopidine
Fluvastatin	Para-aminosalicylate	Timolol
Gold salts	Penicillamine	Tocainide
Griseofulvin	Penicillin	Valproate
Hydralazine	Phenytoin	Verapamil
Hydroxyurea	Phenylbutazone	Zafirlukast
Interferon (α, γ)	Phenelzine	

[a]Drugs in **boldface** represent those with best evidence of association.
Data from references 60 to 64.

rapid improvement of symptoms with a gradual decline in ANAs following drug discontinuation.[60–62] The epidemiologic characteristics of DIL are different from those of idiopathic SLE. In general, patients with procainamide- or hydralazine-induced lupus develop the disease much later in life compared with idiopathic SLE probably because most people who use these drugs are older. There is also an absence of female predominance when compared with idiopathic SLE.

Patients of the slow acetylator phenotype may have a greater risk for developing DIL, particularly with procainamide and hydralazine.[9,60] Procainamide-induced lupus can present as early as 1 month or even after years of therapy. Hydralazine-induced lupus is dose related, leading to the recommended maximum dose of 100 mg/day for men and 50 mg/day for women to minimize the risk of DIL.[63]

Musculoskeletal symptoms are the most common clinical manifestations, while renal manifestations and CNS involvement are rare. Other common features of DIL include fever, fatigue, pericarditis, pleurisy, and weight loss.[64] The classic malar rash is rare in DIL, and skin manifestations are generally less frequent than idiopathic SLE.[60] A positive ANA test is found in nearly all (>90%) hydralazine-induced cases and in 50% to 90% of procainamide-induced disease. The immunofluorescence pattern usually is homogeneous, and antibodies are primarily against ssDNA and not dsDNA as in idiopathic SLE. Antihistone antibodies are specific for DIL but might be found in only 20% of patients with idiopathic SLE.[60]

If signs and symptoms of SLE appear in a patient and are suspected to be drug related, the drug should be discontinued. If the lupus is drug induced, the clinical manifestations should disappear in days to weeks, although it may take up to 1 year or longer for symptoms and serologic abnormalities to resolve completely.[64] A NSAID might be useful in treating musculoskeletal manifestations. Other, more aggressive drug therapy should not be necessary unless manifestations are deemed more serious.

PHARMACOECONOMIC CONSIDERATIONS

Treating patients with SLE is costly, requiring frequent visits to physician offices for monitoring therapy and treating adverse reactions from therapy and hospitalization for disease exacerbation and adverse drug effects. Therefore, it is particularly important in the management of a potentially debilitating chronic disease such as SLE to achieve desired treatment outcomes in an optimal manner to minimize the impact on use of healthcare resources. Costs of treating patients with SLE are slightly higher in the United States compared with Canada and the United Kingdom, but outcomes are similar.[65] The estimated mean annual direct cost in the United States ranges between $10,000 and $14,000 with mediations contributing approximately 26% of direct costs.[66] Direct costs increase with more severe disease, longer disease duration, and worse mental and physical health status.[66]

Disability from lupus also greatly impacts patients' economic status. Indirect disease costs in terms of lost wages are high. In the first year following diagnosis the productivity cost is estimated at approximately $9,000.[66] Work disability ranges from approximately 15% to 51% over 3 to 15 years following diagnosis.[67]

SYSTEMIC SCLEROSIS

CLINICAL MANIFESTATIONS

Systemic sclerosis is characterized by alteration of the microvasculature and by massive deposition of collagen in the skin and internal organs. This disease can present as a spectrum of differing manifestations depending on affected areas and the extent of disease. Sclerosis of the skin is a hallmark for this disease, but other manifestations include a diffuse cutaneous (truncal) systemic sclerosis, with skin tightness and marked skin thickening involving most of the body. Internal organs can also be involved, such as the gastrointestinal tract, lung, kidney, or heart, and can result in death. *Scleroderma* refers to patients with only skin involvement. Disease that affects only the fingers and toes is referred to as *sclerodactyly*.

CLINICAL PRESENTATION OF SYSTEMIC SCLEROSIS

General

- Sclerosis of the skin

Symptoms

- Raynaud's phenomenon
- Dyspepsia
- Constipation
- Diarrhea
- Steatorrhea
- Esophageal dysmotility

Most patients with systemic sclerosis (>95%) have Raynaud's phenomenon, where the digits turn white, followed by a bluish color, which is then followed by reddening in response to an appropriate stimulus. The precipitating event is usually cold temperature or emotion. The pallor is caused by vasospasm, the bluish color is from ischemia, and the reddish color is caused by a reactive hyperemia. Raynaud's phenomenon is a common manifestation of other syndromes, and most patients with Raynaud's phenomenon do not have systemic sclerosis. Gastrointestinal symptoms related to dysphagia and gastroesophageal reflux disease or changes in bowel habits secondary to intestinal dysmotility are common particularly for patients with early disease. In recent years, the lung has emerged as a key target organ in systemic sclerosis. Over 90% of patients have evidence of interstitial lung disease upon autopsy, and 40% demonstrate restrictive changes via pulmonary function tests. Lung involvement is the leading cause of death, and survival is inversely related to the severity of restrictive lung disease.[68,69]

Survival rates are highly variable depending on the extent of disease presentation, organ involvement, and other factors. Systemic sclerosis has the highest mortality rate of all the connective tissue diseases, with a 5-year survival rate estimated as high as 90%[70] and a 10-year survival rate of approximately 55%.[68,69]

ETIOLOGY AND PREVALENCE

The cause of systemic sclerosis is unknown. Ninety-five percent of patients have identifiable autoantibodies. There are two major subsets of the disease: limited cutaneous and diffuse systemic sclerosis. Patients with limited cutaneous involvement often have the Calcinosis, Raynaud's phenomenon, Esophageal dysmotility, Sclerodactyly, and Telangiectasias (CREST) syndrome, whereas patients with diffuse systemic sclerosis have a more aggressive disease with renal, cardiac, or pulmonary involvement. The prevalence of the disease is estimated to be between 4 and 266 cases per 1 million persons.[68,70,71] The wide range may be a result of differences in diagnostic criteria, regional variation, or sample sizes used to estimate the prevalence.

TREATMENT

Systemic Sclerosis

Treatment is empirical because there are no well-controlled trials evaluating and comparing various forms of therapy. Available data are difficult to interpret because of the heterogeneity of the disease, spontaneous remissions that can occur, and lack of objective measures to assess changes in clinical status. D-penicillamine has been used for skin involvement, but data supporting its use remains controversial. Response appears to be best in younger patients, those able to tolerate long-term therapy, and in those with early diagnosis of the disease.[72] Additionally, there seems to be no therapeutic advantage of high-dose (750 to 1,000 mg/day) versus low-dose penicillamine (125 mg every other day) in the treatment of systemic sclerosis according to one multicenter placebo-controlled trial.[69] Response occurs over many months to years, and the drug is not always effective. The high incidence of severe adverse events and the increased dropout rates for D-penicillamine limit its usefulness. Methotrexate appears promising as an effective therapy for skin involvement.[70,73] Evidence from two recent randomized controlled trials suggests that oral or intravenous cyclophosphamide is beneficial for patients with early and progressive interstitial lung disease.[68] Modest improvement in lung function and health-related outcomes (dyspnea and skin thickening among others) were demonstrated after 1 year of cyclophosphamide therapy with or without subsequent treatment with azathioprine and prednisone.[68,74–76] Mycophenolate mofetil also has demonstrated modest benefit in multiple small studies, but controlled trials are lacking.[68,69] Antiinflammatory agents and corticosteroids have not been effective in systemic sclerosis.

Angiotensin-converting enzyme (ACE) inhibitors have improved survival dramatically for patients with renal involvement and improve outcomes for patients with disease-associated pulmonary hypertension or myocardial involvement.[68,69,77] Patients with sclerosis of the kidneys develop hypertension, leading to a renal crisis. For these patients, plasma renin activity and angiotensin concentrations can be more than twice normal. Renal involvement should be anticipated in all systemic sclerosis patients who develop hypertension. Patients with systemic sclerosis and hypertension should be treated and maintained with an ACE inhibitor regardless of renal involvement. ACE inhibitors should be used for patients on dialysis, and they have allowed some dialysis-dependent systemic sclerosis patients to discontinue dialysis.[69,77,78] Angiotensin receptor blockers are less effective than ACE inhibitors but may have an additive effect to ACE inhibitors in refractory cases.[78] Treatment of Raynaud's phenomenon requires patient education and sometimes drug therapy. Patients must maintain their peripheral extremity and core body temperatures. Wearing appropriate clothing in cold environments is essential. Reaching into a freezer with unprotected hands should be avoided. Drugs that can cause peripheral vasoconstriction, such as pseudoephedrine and β-blockers, should be avoided for patients with Raynaud's phenomenon or systemic sclerosis. Smoking causes cutaneous vasoconstriction and should be eliminated, and this includes passive smoke. When preventive measures are insufficient, aggressive oral vasodilator therapy is useful for decreasing the frequency and severity of Raynaud's phenomenon episodes and may limit peripheral vascular (ischemic) complications. Commonly used agents are calcium channel blockers (nifedipine) and angiotensin receptor blockers (losartan).[68,70,73] Although there are limited data, other agents that may be beneficial for Raynaud are selective serotonin reuptake inhibitors (fluoxetine), phosphodiesterase-5 inhibitors (sildenafil), and endothelin-1 receptor antagonists (bosentan).[68–70]

INFLAMMATORY MYOPATHIES

CLINICAL MANIFESTATIONS

The inflammatory myopathies are a heterogeneous group of relatively rare, chronic, inflammatory muscle diseases of unknown etiology. The major types of inflammatory myopathies are polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM). A fourth subtype, immune mediated necrotizing myopathy (NM), clinically resembles PM but has minimal inflammatory cell infiltrates on muscle biopsy.[79] DM is distinguished from PM by a typical rash, which is red, scaly, and plaque-like, over the knuckles, wrists, elbows, and knees and typically precedes or accompanies the onset of muscle weakness. A blue-purple discoloration on the upper eyelids with edema also can occur in DM. Patients with inflammatory myopathies generally present with progressive weakness. In DM, PM, and NM the heart (pericarditis leading to heart failure or arrhythmia) and lungs (interstitial lung disease) may be affected, and patients may present with dysphagia and/or dyspnea.[79,80] There is an increased risk of malignancy associated with PM, NM, and particularly DM.

An increased serum creatine kinase concentration and electromyography abnormalities are common. Other serum enzymes, such as the alanine transaminase, aspartate transaminase, and lactate dehydrogenase, also may be increased.[79,81] Muscle biopsies show either characteristic inflammatory cell infiltrates (PM, DM, and IBM) or necrotic muscle fibers (NM). ANAs are detected in 24% to 60% of DM, 16% to 40% of PM, and up to 20% of IBM patients. Some patients develop certain "myositis specific antibodies" as well.[79]

CLINICAL PRESENTATION OF POLYMYOSITIS AND DERMATOMYOSITIS

General

- Inflammation of skeletal muscle and skin

Symptoms

- Muscle weakness in shoulder and hip girdles and trunk
- Insidious onset
- Arthritis, Raynaud's phenomenon, and other symptoms of connective tissue diseases

TREATMENT

Inflammatory Myopathies

DM, PM, and NM patients usually respond to immunotherapies, while IBM patients usually do not.[79] A few small, randomized, double-blind, placebo-controlled trials evaluating the treatment of PM, DM, and IBM have been conducted, but evidence supporting use of drug therapy in large controlled trials is still lacking. It does appear that various immunotherapies may be helpful in both PM and DM. The goal of therapy is to increase muscle strength so as to improve function in activities of daily living (e.g., bathing, dressing, feeding, and toileting). Treatment consists of physical therapy during periods of remission and rest during periods of disease activity. Prednisone is the first line of drug therapy for PM and DM. Although the optimal dose of prednisone is not clear, most clinicians use prednisone at a starting dose of 60 to 100 mg/day or about 1 mg/kg per day as a single morning dose.[81] Higher prednisone doses of 1.5 mg/kg per day can be used

if needed. The initial dose of prednisone is continued for at least 2 to 4 weeks or until maximum benefit is achieved or a remission is induced. The full effect of prednisone may not be evident for several months. After 4 months of treatment, approximately 85% of patients treated with prednisone will have normal muscle strength. The prednisone dose is tapered when muscle strength improves and serum creatine kinase concentrations decrease. If the patient is responding to prednisone and there are no serious side effects, the drug is tapered slowly over about 2 to 3 months and finally to a lower maintenance dose that may be alternate daily dosing if tolerated. The dose that maintains a good clinical response can be used as maintenance. Tapering too quickly can cause an exacerbation of disease activity. Monitoring serum creatine kinase concentrations is useful because they tend to increase several weeks before clinical symptoms become apparent. Some clinicians will treat patients with daily prednisone for 1 or more years, whereas others may use every-other-day therapy for many years.[79,81]

One complication from corticosteroid use is the development of a myopathy. Based on symptoms, it is difficult to know if increased muscle weakness is caused by the corticosteroid or to worsening disease status. Lowering the prednisone dose may be useful. If patients get better on a lower dose of prednisone, then most likely the muscle weakness was caused by the drug. It may take 2 to 8 weeks for this to become evident clinically. Use of serum creatine kinase concentration also may be helpful because this does not increase with steroid myopathy. It is possible that a steroid myopathy and worsening disease can coexist.

Although most patients with PM or DM improve with prednisone, some will not, and some will develop corticosteroid resistance. In these patients and in those in whom a complete response is not achieved, azathioprine may be used at a dose of 2 to 3 mg/kg per day as a single morning dose.[79] Clinical response may take 3 to 6 months. Another alternative is methotrexate at a dose of 7.5 to 20 mg once weekly. For patients resistant to these therapies, cyclophosphamide, cyclosporine, mycophenolate mofetil or rituximab can be tried.[79,80] Intravenous immunoglobulin (IVIG) at a dose of 2 g/kg every 1 to 2 months may be effective for patients with refractory disease not responding to prednisone/azathioprine therapy. Evidence from one randomized controlled trial for DM patients supports the use of IVIG in these patients.[80] Alternative therapies are often used in PM or DM, but there is no convincing evidence to support their use. These alternative therapies also may be beneficial for patients who can not take corticosteroids because of serious adverse effects.

POLYMYALGIA RHEUMATICA AND GIANT-CELL ARTERITIS

CLINICAL MANIFESTATIONS

Polymyalgia rheumatica (PMR) and giant-cell arteritis (GCA) are closely related diseases, and some experts consider them to be different phases of the same disease.[82,83]

PMR is a disease characterized by severe bilateral pain and aching in the shoulders, neck, and pelvic girdles with associated morning stiffness. Systemic symptoms such as low-grade fever, fatigue, and weight loss are frequently present.[84] GCA is a vasculitis of large- and medium-size vessels; it is the most common type of vasculitis in North America and Europe.[85] The most frequent symptom of GCA is headache, with bilateral pain usually in the temporal or occipital areas; signs of systemic inflammation are also usually present.[83,84,86] GCA was referred to previously as *temporal arteritis* or *granulomatous arteritis*. Both PMR and GCA occur in people older than 50 years of age, and the incidence increases with age, peaking between ages 70 and 80 years.[83,84] Some patients go from exhibiting no symptoms to overt clinical manifestations overnight, whereas others have a gradual onset of symptoms over a number of weeks. The etiology is unknown.

TREATMENT

Polymyalgia Rheumatica and Giant-Cell Arteritis

The treatment of choice for both PMR and GCA is a corticosteroid, mainly prednisone.[83,84] Several different dosing regimens have been studied, but a recent systematic review of PMR treatment studies published in the primary literature concluded that a starting dose of 15 mg/day of prednisone appears effective in most PMR patients and that once initial remission (control of symptoms) was achieved, the prednisone dose should be tapered slowly based on clinical symptoms and laboratory parameters [e.g., erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels]. Additionally, once a stable prednisone maintenance dose of 10 mg/day was achieved, further dose reductions should be smaller than 1 mg per month (e.g., 1 mg every 2 months). The authors also concluded that despite the differences in starting doses and tapering protocols studied, prednisone doses between 10 and 20 mg/day appeared to control symptoms at PMR onset and generally allowed for corticosteroid therapy discontinuation for about half of patients after 2 years of treatment.[84] Usually the response to steroids is quite rapid, with complete or nearly complete symptom resolution within a few days. In fact, corticosteroid therapy is so effective that if improvement does not occur within a week, another diagnosis should be considered.[87] The prednisone should be tapered beginning 2 to 4 weeks following control of symptoms. The rate of tapering is based on clinical response. A taper of 2.5 mg/day at 2- to 4-week intervals to 10 mg/day followed by a slower tapering of 1 mg/day at monthly intervals has been suggested.[87,88] The lowest dose of prednisone that controls symptoms should be used for maintenance. Patients usually continue maintenance therapy for 1 to 3 years. Patients may experience a relapse when the prednisone is discontinued. For patients with GCA without visual or neurological symptoms but with systemic and inflammatory symptoms, daily prednisone doses of 40 to 60 mg (or 1 mg/kg/day) are generally used. Higher doses are recommended for patients with acute visual or neurological signs or symptoms (at least 80 mg/day or up to 2 mg/kg/day). In fact, it is common to hospitalize more acutely ill patients and start intravenous steroids such as methylprednisolone 250 mg every 6 hours for the first 3 to 5 days, then switch to high dose oral prednisone. High-dose prednisone is maintained for at least 4 to 6 weeks until systemic symptoms have diminished and laboratory markers of inflammation (ESR and CRP) have normalized. A slow taper should follow, and a maintenance dose of 7.5 to 10 mg/day is generally achieved in 6 to 12 months. Patients may require 1 to 5 years of steroid therapy.[83] Because these are diseases of the elderly, it is particularly important to use calcium and vitamin D supplements to prevent corticosteroid-induced osteoporosis. Prophylactic bisphosphonate therapy also should be considered. Unlike most other autoimmune diseases, other forms of immunosuppressive therapy are not as effective as corticosteroids in PMR and GCA.[86] However, there is evidence supporting methotrexate as a glucocorticoid-sparing agent when used to treat patients with

PMR in conjunction with prednisone.[84] Studies examining the role of methotrexate in treating patients with GCA have yielded conflicting results.[83]

CLINICAL PRESENTATION OF POLYMYALGIA RHEUMATICA AND GIANT-CELL ARTERITIS

General

- Aching and morning stiffness of neck, shoulder, and pelvic girdle musculature and torso.

Symptoms

- Pain and morning stiffness lasting 1 to 6 hours
- Fatigue, malaise, and weight loss usually present
- Anorexia
- Headache in GCA

Signs

- Low-grade fever

Laboratory Tests

- Erythrocyte sedimentation rate is generally >40 mm/h (11.1 μm/s) and often >100 mm/h (27.8 μm/s)

DRUG-INDUCED VASCULITIS

CLINICAL MANIFESTATIONS

Drugs are common causes of vasculitis, often occurring in the skin, but other organ involvement (kidney and lung in particular) can occur. The pathogenesis of inflammation of blood vessel walls caused by drugs is poorly understood. Even drugs used to treat inflammatory and immune-mediated disease, such as NSAIDs, sulfasalazine, and etanercept, can cause vasculitis.[89]

CLINICAL PRESENTATION OF DRUG-INDUCED VASCULITIS

General

- Signs and symptoms depend on organ involvement

Symptoms

- Rash
- Glomerulonephritis
- Hepatitis
- Fatigue
- Myalgia
- Arthralgia

Signs

- Fever

Long-term use of the offending agent is thought to be a risk factor for developing vasculitis, but length of use varies widely in case reports. Most classes of medications have been reported to cause vasculitis.[90] Although there are no specific diagnostic tests for drug-induced vasculitis, antineutrophil cytoplasmic autoantibodies have been identified in many cases of drug-induced vasculitis.[89,90] ESR and CRP are often elevated in drug-induced vasculitides; anemia may be present as well.[89]

TREATMENT

Drug-Induced Vasculitis

6 The first step in therapy of drug-induced vasculitis is to discontinue the suspected inducing agent. This may be all that is necessary to abate symptoms in mild cases. For more serious cases, corticosteroids may be used, and where life-threatening organ involvement occurs, immunosuppressive therapy with agents such as cyclophosphamide or mycophenolate mofetil may be used. Following therapy, symptoms usually resolve within 1 to 4 weeks, except in cases of significant organ involvement.[89]

EVALUATION OF THERAPEUTIC OUTCOMES

The diversity of clinical features and disease severity associated with the collagen–vascular diseases leads to a number of possible clinical outcomes with a broad range of desired therapeutic outcomes. Achieving desired therapeutic outcomes for most of the collagen–vascular diseases is highly variable. Currently, it is not possible to predict which patients will have a satisfactory therapeutic response and which will have unrelenting progressive disease. These diseases often have fluctuating courses, necessitating frequent changes in drug therapy and drug doses.

Evaluation of drug therapy of several of the collagen–vascular diseases often only requires monitoring for resolution of symptoms such as rash or muscle pain. However, patients with life-threatening disease receiving aggressive pharmacotherapy may require intensive monitoring and evaluation of therapy. For example, the patient receiving cytotoxic drug therapy for severe lupus nephritis requires close monitoring of laboratory indices of renal function, as well as monitoring of symptomatology and laboratory indices for possible bone marrow suppression, infection, cystitis, or other potential adverse effects.

Evaluation of therapeutic outcomes also should include an awareness of the possibility of drug therapy mimicking signs and symptoms of disease, such as the lupus patient receiving NSAID therapy and presenting with renal insufficiency or the patient with PM receiving prednisone and presenting with an exacerbation of muscle weakness.

As patients live longer, as is the case with SLE, outcome measures other than mortality will be needed to assess the effect of treatment. Clinicians and researchers working with lupus patients have developed and continue to refine some of these alternative outcome measures. Three important domains for assessing lupus patients are disease activity, accumulated damage, and quality of life.[91] Table 96–7 lists several instruments useful for assessing patients with SLE.

TABLE 96-7 Instruments Used for Assessing Outcome Measures in Patients with Systemic Lupus Erythematosus

Outcome Domain	Instrument
Disease activity	Systemic Lupus Activity Measure (SLAM)/SLAM Revised (SLAM-R)
	Systemic Lupus Erythematosus Disease Activity Index (SLEDAI)
	European Community Lupus Activity Measure (ECLAM)
	British Isles Lupus Activity Group (BILAG)
	Lupus Activity Index (LAI)
Accumulated damage	Systemic Lupus International Collaborating Clinics/American College of Rheumatology (SLICC/ACR) damage index

Data from reference 91.

CONCLUSION

SLE is a disease that affects multiple organ systems and consists of abnormal immunologic function and the development of autoantibodies. The disease is quite variable in clinical presentation and progression. The cause of lupus is unknown, although several factors (e.g., genetics, environment, and hormones) may predispose an individual to the development of the disease. Although SLE was once thought to be rapidly fatal, today nearly 90% of patients survive 10 years.

Drug therapy is nonspecific and is aimed at suppressing the inflammation and abnormal immune response associated with active disease. Clinical trials with various agents often have been inadequate and contradictory, and the therapeutic management of lupus is not optimal. Nevertheless, drug therapy of recent years probably has contributed significantly to the improved survival of these patients. As the understanding of SLE progresses and advances in molecular biology occur, we can expect to see the development of more specific and optimal treatment and further improvement in survival.

Each of the collagen–vascular diseases has its own recommended form of therapy. For most of these diseases, there are few well-controlled clinical trials evaluating pharmacotherapy. Treatment of most of these diseases requires antiinflammatory or immunosuppressive drugs. Monitoring therapeutic outcomes is essential because drugs and drug doses may need to be modified frequently.

ABBREVIATIONS

ACE: angiotensin-converting enzyme

ANA: antinuclear antibodies

CAD: coronary artery disease

CRP: C-reactive protein

DIL: drug-induced lupus

DM: dermatomyositis

DNA: deoxyribonucleic acid

dsDNA: double-stranded DNA

ESR: erythrocyte sedimentation rate

IVIG: intravenous immunoglobulin

NSAID: nonsteroidal antiinflammatory drug

PM: polymyositis

PMR: polymyalgia rheumatica

RNP: ribonucleoprotein

SLE: systemic lupus erythematosus

ssDNA: single-stranded DNA

RNA: ribonucleic acid

CHAPTER 97

Allergic and Pseudoallergic Drug Reactions

LYNNE M. SYLVIA AND JOSEPH T. DIPIRO

KEY CONCEPTS

1. Hypersensitivity reactions are responsible for 6% to 10% of adverse reactions to medications. Although some reactions are relatively well defined, the majority are due to mechanisms that are either unknown or poorly understood.
2. The following criteria suggest that a drug reaction may be immunologically mediated: (a) the reaction occurs in a small percentage of patients receiving the drug, (b) the observed reaction does not resemble the drug's pharmacologic effect, (c) the type of manifestation is similar to that seen with other allergic reactions (anaphylaxis, urticaria, serum sickness), (d) there is a lag time between first exposure of the drug and reaction, (e) the reaction is reproduced even by minute doses of the drug, (f) the reaction is reproduced by agents with similar chemical structures, (g) eosinophilia is present, or (h) the reaction resolves after the drug has been discontinued. Exceptions to each of these criteria are observed commonly.
3. Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that generally begins within 30 minutes but almost always within 2 hours after exposure to the inciting allergen. Anaphylaxis requires prompt treatment to restore respiratory and cardiovascular function. Epinephrine is administered as primary treatment to counteract bronchoconstriction and vasodilation. Intravenous fluids should be administered to restore intravascular volume.
4. Factors that influence the likelihood of allergic drug reactions are the chemical composition of the drug, whether the drug contains proteins of nonhuman origin, the route of drug administration, and the sensitivity of the individual as determined by genetics, or environmental factors. For some drugs, genetic predisposition to specific HLA alleles has been identified as a risk factor for allergic-mediated skin reactions.
5. Patients with a history of an immediate reaction to penicillin are advised not to receive cephalosporins if they can be avoided. Patients who have negative penicillin skin tests or experienced only mild cutaneous reactions, such as maculopapular rashes, have a low risk of serious reactions to cephalosporins.
6. Less than 1% of patients receiving nonionic radiocontrast agents experience some type of adverse reaction. Of the variety of reactions reported, approximately 90% are allergic like, mostly urticarial, with severe reactions occurring as infrequently as 0.02%.
7. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can produce two general types of reactions, urticaria/angioedema and rhinosinusitis/asthma, in susceptible patients. About 20% of asthmatics are sensitive to aspirin and other NSAIDs.
8. Cross-reactivity between sulfonamide antibiotics and nonantibiotics is low. The low cross-reactive rate may be explained by differences in the chemical structures and reactive metabolites of the sulfonamide antibiotics and nonantibiotics.
9. The basic principles of management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible, (b) treatment of the adverse clinical signs and symptoms, and (c) substitution, if necessary, of another agent.
10. One of the most helpful tests to evaluate risk of penicillin allergy is the skin test. Skin testing can demonstrate the presence of penicillin-specific immunoglobulin E and predict a relatively high risk of immediate hypersensitivity reactions. Skin testing does not predict the risk of delayed reactions or most dermatologic reactions.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 *Allergic drug reactions, also known as hypersensitivity reactions*, result from an over-response of the immune system to the standard dose of a drug. The hyper-response of the immune system to the antigenic drug leads to host tissue damage manifesting as an organ-specific or generalized systemic reaction. Adverse drug effects not proven to be immune mediated but resembling allergic reactions in their clinical presentation are referred to as *allergic-like* or *pseudoallergic reactions*. Immunologically mediated adverse drug reactions account for 6% to 10% of all adverse drug reactions and even up to 15% by some estimates.[1,2] Examples of allergic drug reactions are anaphylaxis from β-lactam antibiotics, halothane hepatitis, Stevens Johnson syndrome from sulfonamides, allopurinol hypersensitivity syndrome and serum sickness from phenytoin.[3] Examples of pseudoallergic reactions are shock after radiocontrast media, aspirin-induced asthma, opiate-related urticaria, and flushing after vancomycin infusion.[3]

The true frequency of allergic drug reactions is difficult to determine because many reactions may not be reported, and others may be difficult to distinguish from nonallergic adverse events. Dermatologic reactions represent the most frequently recognized and reported form of allergic drug reaction.[4]

TABLE 97-1 Classification of Allergic Drug Reactions

Type	Descriptor	Characteristics	Typical Onset	Drug Causes
I	Anaphylactic (IgE mediated)	Allergen binds to IgE on basophils or mast cells, resulting in release of inflammatory medicators.	Within 30 min to <2 hours	Penicillin immediate reaction Blood products Polypeptide hormones Vaccines Dextran
II	Cytotoxic	Cell destruction occurs because of cell-associated antigen that initiates cytolysis by antigen-specific antibody (IgG or IgM). Most often involves blood elements.	Typically >72 h	Penicillin, quinidine, heparin, phenylbutazone, thiouracils, sulfonamides, methyldopa
III	Immune complex	Antigen–antibody complexes form and deposit on blood vessel walls and activate complement. Result is a serum sickness-like syndrome.	>72 h	May be caused by penicillins, sulfonamides, minocycline, hydantoins
IV	Cell-mediated (delayed)	Antigens cause activation of T lymphocytes, which release cytokines and recruit effector cells (e.g., macrophages, eosinophils).	>72 h	Tuberculin reaction Maculopapular rashes to a variety of drugs; Contact dermatitis Bullous exanthems Pustular exanthems

MECHANISMS OF ALLERGIC DRUG REACTIONS

Drugs can cause hypersensitivity reactions by a variety of immunologic mechanisms. Although some reactions are relatively well defined, most are due to mechanisms that are either unknown or poorly understood.[2,3]

2 The following criteria suggest that a drug reaction may be immunologically mediated: (a) the observed reaction does not resemble the drug's pharmacologic effect, (b) there is a lag time between first exposure of the drug and reaction unless the recipient has been sensitized by prior exposure to the drug, which can lead to immediate reactions, (c) the reaction may occur even by minute doses of the drug, (d) the symptoms are characteristic of an allergic reaction (e.g., anaphylaxis, urticaria, serum sickness), (e) the reaction resolves after the drug has been discontinued, and (f) the reaction may be reproduced by agents with similar chemical structures.[2] Exceptions to each of these criteria are observed commonly. Many allergic reactions can be classified into one of four immunopathologic categories: type I, II, III, or IV (Table 97–1 and Fig. 97–1).[2,3]

EFFECTORS OF ALLERGIC DRUG REACTIONS

Allergic drug reactions can involve most of the major components of the innate and adaptive immune systems, including the cellular elements, immunoglobulins, complement, and cytokines. Most immunoglobulin isotypes have been implicated in immunologically mediated drug reactions. Immunoglobulin E (IgE) bound to basophils or mast cells mediates immediate (anaphylactic-type) reactions. IgG or IgM antibodies also may be involved in allergic reactions, resulting in destruction of cells and tissues. T lymphocytes have a major role in hypersensitivity reactions and are involved in all four types (I–IV) of the drug hypersensitivity reactions described by Coombs and Gell.[2,5,6]

CELLULAR ELEMENTS

A variety of cells are involved in drug hypersensitivity. Antigen-presenting cells (APCs) include macrophages, dendritic cells, and cutaneous Langerhan cells. APCs process the antigenic drug for subsequent recognition by T and B lymphocytes. Basophils and mast cells are instrumental in the development of immediate hypersensitivity reactions, whereas eosinophils are recruited in both immediate and nonimmediate reactions. Platelets and vascular endothelial cells are important because they also can release a number of inflammatory mediators.[7] Most cells of the body, including nerve cells, can become involved directly or indirectly in allergic drug reactions.

MEDIATORS OF ALLERGIC REACTIONS

The release of a number of preformed, pharmacologically active chemical mediators (e.g., histamine, heparin, proteases such as

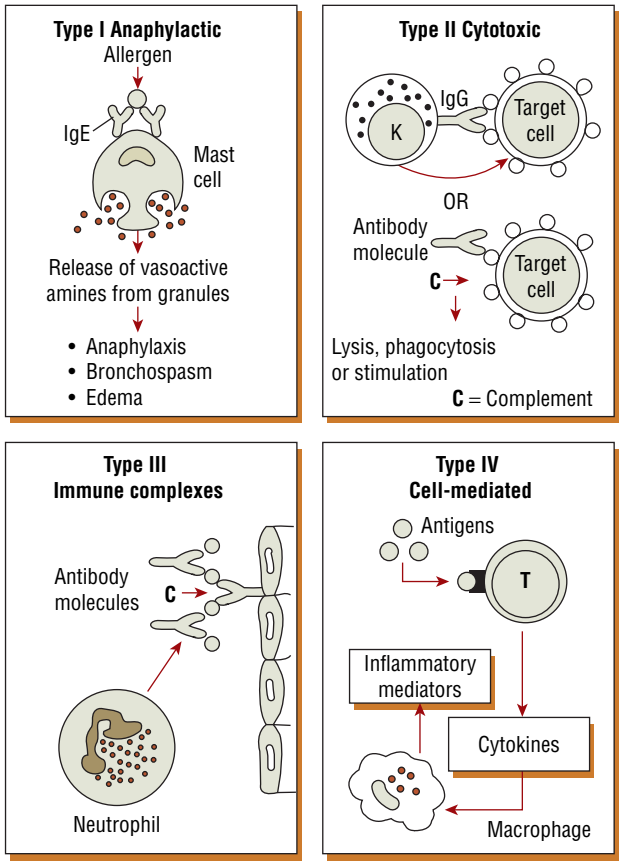

FIGURE 97-1. Types of hypersensitivity reactions.

tryptase and chymase, and a variety of other enzymes) is triggered when antigens cross-link IgE molecules on the surface of circulating basophils and tissue mast cells. Newly formed mediators include platelet-activating factor and arachidonic acid metabolites (e.g., prostaglandins, thromboxanes, and leukotrienes).

Histamine is a low-molecular-weight amine compound formed by decarboxylation of histidine and is stored in basophil and mast cell granules.[8] Release of histamine from these cells is triggered by antigen cross-linking IgE bound to specific receptors on the surface membranes of mast cells and basophils. The tissue effects of histamine are evident within 1 to 2 minutes, but it is rapidly metabolized within 10 to 15 minutes. The major effects of histamine on target tissues include increased capillary permeability, contraction of bronchial and vascular smooth muscle, and hypersecretion of mucus glands. Four classes of histamine receptors (H_1–H_4) are present to varying degrees in organs and tissues. H_1 receptors are most prominent in blood vessels and bronchial and intestinal smooth muscle.

Platelet-activating factor (PAF) is a glyceride-derived substance that is released by mast cells, alveolar macrophages, neutrophils, platelets, and other cells but not by basophils. It has potent bronchoconstrictor effects and causes platelet aggregation and lysis. It attracts neutrophils and causes their activation. PAF enhances vascular permeability and can cause pain, pruritus, and erythema.

The leukotrienes (LTs) are metabolites of arachidonic acid produced through the 5-lipoxygenase pathway that have potent effects on bronchial and vascular smooth muscle. Three important leukotrienes, LTC_4, LTD_4, and LTE_4, are produced by basophils or mast cells. These three substances are also referred to as *cysteinyl leukotrienes* and in older literature as *slow-reacting substances of anaphylaxis*. The LTs have more potent and longer-lasting bronchoconstrictor effects than histamine and can increase vascular permeability and cause arteriolar vasoconstriction followed by vasodilation. Their effects are slower in onset but longer lasting than those of histamine. Another product, LTB_4, is a potent chemoattractant, particularly for neutrophils. It is also produced by neutrophils, macrophages, and monocytes.

Prostaglandins (PGs) and thromboxanes are metabolites of arachidonic acid produced through the cyclooxygenase pathway. Some PGs have vasoconstrictive and/or bronchodilatory properties, whereas others are vasodilatory and/or bronchoconstrictive. PGD_2 is the major PG product of mast cells. It is a potent inhibitor of platelet aggregation and is a bronchoconstrictor. Thromboxanes cause platelet aggregation and are important regulators of coagulation.

The complement system consists of approximately 30 plasma proteins and is involved in hypersensitivity through a variety of immunologic responses, including enhancement of phagocytosis (opsonization of target cells), cell lysis, and generation of anaphylatoxins (C3a, C4a, and C5a), which can cause non–IgE-mediated activation of mast cells and release of inflammatory mediators.

CLASSIFICATION OF IMMUNOPATHOLOGIC DRUG REACTIONS

Immunologic mechanisms have been identified for some drug reactions, and many can be classified into one of four immunopathologic reactions, first described by Coombs and Gell. Small-molecular-weight molecules (<10 kDa) do not have the ability to serve as antigens on their own. With the exception of polypeptide compounds, most drugs are <1,000 Da. To become immunogenic, these small compounds must first covalently bind to carrier proteins in plasma or tissue. The combination of the drug bound to a carrier protein can be recognized as foreign by APCs and T lymphocytes, culminating in an immune response. The more likely that large amounts of the drug become chemically bound to a protein, the greater the risk of producing an allergic reaction. Penicillin G (356 Da) is an example of a drug that binds covalently to serum proteins through amide or disulfide linkages. For drugs such as the sulfonamides, the parent compound first must be converted to a metabolite before it can combine with the macromolecule. The species that combines with the carrier macromolecule is referred to as a *hapten* or an *incomplete antigen*.[9] Some macromolecular drugs such as insulin are referred to as *complete antigens* because they are large enough to initiate an immune response without binding to another protein. Some small-molecular-weight drugs may cause an immune response through a non-hapten pathway.[5] Known as the p-i concept, this pathway involves a pharmacological interaction between the drug and the T-cell receptor that does not require the initial binding of the drug to a carrier protein or processing by APCs.[6]

TYPE I

Type I reactions require the presence of IgE specific for the drug or the portion of the drug that becomes a hapten. IgE specific for the drug allergen is produced on initial exposure to the drug. It then binds to basophils and mast cells through high-affinity receptors. On repeat exposure to the drug, two or more IgE molecules on the basophil or mast cell surface may bind to one multivalent antigen molecule (referred to as *cross-linking;* see Fig. 97–1), initiating an activation of the cell. Activation causes the extracellular release of granules with preformed inflammatory mediators, including histamine, heparin, proteases (tryptase in the mast cell), as well as generation of newly formed mediators, as previously discussed, such as LTs, PGs, thromboxanes, and PAF, among others.

Generation of a type I reaction can be evident as an immediate hypersensitivity reaction, or anaphylaxis. Immediate reactions may be limited to single organs, typically in the nasal mucosa (rhinitis), respiratory tract (acute asthma), skin, or gastrointestinal tract, or they can involve multiple organs simultaneously, termed *anaphylaxis*.

TYPE II

Type II immunopathologic reactions involve destruction of host cells (usually blood cells) through cytotoxic antibodies by one of two mechanisms (see Fig. 97–1). First, the drug binds to the cell as a hapten (e.g., the platelet or red blood cell). Antibodies (IgG or IgM) specific for the bound drug or to a component of the cell surface that has been altered by the drug then bind, initiating a cytolytic reaction. Cell destruction may be mediated by complement or by phagocytic cells that have antibody Fc receptors on their surfaces. Activation of complement near the cell surface can result in loss of cell membrane integrity and cell death. Alternatively, neutrophils, monocytes, or macrophages may bind to an antibody-coated cell through IgG Fc receptors on their cell surfaces, resulting in phagocytosis of the target cell. The process of enhancement of phagocytosis by antibody binding to cell surfaces or other particles is referred to as *opsonization*. In addition, cell-bound IgG may direct the non-phagocytic action of T cells or natural killer cells, which results in cell destruction by a process called *antibody-dependent cellular cytotoxicity*. This process can proceed in a nonspecific fashion as T cells bind to the target cell through IgG Fc receptors on the T-cell surface. Contact between the target and effector cells is necessary.

Cells commonly affected by these types of reactions include erythrocytes, leukocytes, and platelets, resulting in hemolytic anemia, agranulocytosis, or thrombocytopenia, respectively. This process

may be initiated by drugs such as penicillin, quinidine, quinine, phenacetin, cephalosporins, and sulfonamides.

Another type of reaction that may affect the formed elements in blood is the "innocent bystander" reaction. With this type of reaction, antigen–antibody complexes formed in blood adhere nonspecifically to cells. Complement is then activated, resulting in cell lysis.

TYPE III

Type III immunologic reactions are caused by antigen–antibody complexes that are formed in blood. The complexes form with drug allergen and antibody in varying ratios and may deposit in tissues, resulting in local or disseminated inflammatory reactions. Antigen–antibody complex formation can result in platelet aggregation, complement activation, or macrophage activation. Chemotactic substances such as C4a also are produced. These substances cause the influx of neutrophils and result in the release of a number of toxic substances from the neutrophil (e.g., proteinases, collagenases, kinin-generating enzymes, and reactive oxygen and nitrogen substances), which can cause local tissue destruction.

Platelet aggregation may occur as a result of immune-complex formation, resulting in the formation of microthrombi and the release of vasoactive mediators. Also, insoluble complexes may be phagocytized by macrophages and activate these cells.

The formation of antigen–antibody complexes can lead to clinical syndromes such as the Arthus reaction. In this model, a high level of preformed specific IgG antibody combines with antigen to produce a localized edematous, erythematous reaction within 5 to 8 hours. The reaction involves local formation of insoluble antigen–antibody complexes, complement activation with release of C3a and C5a collectively referred to as *anaphylatoxins,* mast cell degranulation, and influx of polymorphonuclear cells.

TYPE IV

Type IV reactions are delayed hypersensitivity reactions that typically are demonstrated as dermatologic events mediated by T cells ($CD4^+$ or $CD8^+$).[5,6] The Coombs and Gell classification of allergic drug reactions was developed prior to our understanding of the varied roles of T cells in the immune response. Four subclasses of type IV reactions (IVa–IVd) have been described.[5,6] In this subclassfication system, type IV reactions are differentiated based on the responding T cell (e.g., T helper type 1 cell, T helper type 2 cell, cytotoxic T cell), effector mechanism (e.g., recruitment of macrophages, eosinophils, or neutrophils) and clinical manifestations (e.g., contact dermatitis, bullous exanthems, maculopapular eruptions, pustular exanthems).[5,6] Type IV reactions require memory T cells specific for the antigen in question. On exposure to the antigen, the immune response is mediated by a specific subtype of T cell that orchestrates an inflammatory response through the secretion of cytokines and the recruitment of effector cells. These reactions are associated with a wide variety of adverse effects (e.g., contact dermatitis, maculopapular exanthemas, bullous exanthemas, eczema, or pustular exanthemas), and they also may be useful for diagnostic purposes. Examples of the latter include the purified protein derivative (PPD) antigen from *Mycobacterium tuberculosis* used in the tuberculin skin test and other recall skin test antigens, such as mumps. After intradermal injection, these antigens produce a local reaction (erythema and induration) within 48 to 72 hours. Delayed contact hypersensitivity also can be caused by a wide variety of chemicals and drugs.

OTHER ALLERGIC REACTIONS

The precise mechanism of many drug reactions is not known, although the reactions are believed to be immune mediated. Perhaps most common are the delayed dermatologic reactions that occur with a variety of drugs (especially penicillins and sulfonamides). These reactions may be evident as fixed drug eruptions, macropapular, morbilliform, or erythematous rashes; exfoliative dermatitis; photosensitivity reactions; or eczema. These reactions also may be manifest as late onset pruritus, urticaria, and angioedema.

A number of serious cutaneous adverse reactions, known as SCARs, may be the result of immunologic reactions. SCARs include drug rash with eosinophilia and systemic symptoms (DRESS) and the mucocutaneous disorders, Stevens Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). Drug-induced fever also may involve immunologic mechanisms. Other general types of reactions believed to be immune mediated in some cases include hepatic drug reactions (cholestatic or hepatocellular) and pulmonary reactions, for example, interstitial pneumonitis, which has been associated with nitrofurantoin.

ANAPHYLACTOID REACTIONS

Various drugs and other substances can produce anaphylactoid (anaphylaxis-like) reactions that are similar to anaphylaxis in clinical signs and symptoms. The substances causing these reactions can lead to the direct release or activation of inflammatory mediators from cells by a pharmacologic or physical effect rather than through cell-bound IgE. These reactions are the most severe form of pseudoallergy, but not all pseudoallergic reactions are anaphylactoid. Pseudoallergy refers to a wide array of reactions ranging from localized hives to life-threatening angioedema, hypotension, and anaphylaxis, all of which are explained by the nonimmunologic release or activation of inflammatory mediators. Drugs that can produce anaphylactoid reactions include vancomycin, opiates, iodinated radiocontrast agents, angiotensin-converting enzyme inhibitors, amphotericin B, and D-tubocurarine. The "red man syndrome" is a common example of a pseudoallergic reaction from vancomycin. If vancomycin is infused too rapidly, it can cause the direct release of histamine and other mediators from cutaneous mast cells, producing a typical clinical picture of itching, flushing, and hives, first around the neck and face and then progressing to the chest and other parts of the body usually beginning shortly after the infusion has begun. In some cases, the cutaneous manifestations of "red man syndrome" may be accompanied by hypotension, thereby constituting an anaphylactoid event. Most patients who have had "red man syndrome" will tolerate vancomycin if the rate of infusion is slowed. In rare cases, the severity of the reaction may preclude continued therapy with vancomycin. A number of other agents (including aspirin) may produce anaphylactoid reactions by altering the metabolism of inflammatory mediators such as PGs or kinins. Angioedema from angiotensin-converting enzyme inhibitors is a classic example of an anaphylactoid reaction. Although the mechanism by which this anaphylactic-like event occurs is not fully understood, inhibition of the breakdown of bradykinin and substance P by the angiotensin-converting enzyme inhibitor may explain the inflammation, increased vascular permeability and vasodilation.

CLINICAL MANIFESTATIONS OF ALLERGIC AND ALLERGIC-LIKE REACTIONS

ANAPHYLAXIS

3 Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that occurs in 10 to 20 per 100,000 population per year.[10,11] Approximately 1,500 deaths from anaphylaxis occur annually in the United States.[12] From 1.2% to 15% of the U.S. population may be at risk for anaphylactic reactions.[13]

Although many drugs may cause anaphylaxis (or anaphylactoid) reactions, the most commonly reported are penicillins, aspirin and other NSAIDs, and insulins.[10] In most patients, the initial signs and symptoms are referable to the skin (flushing, pruritus, urticaria, angioedema). The second most common symptoms are respiratory (tightness of the throat and chest, dysphagia, dysphonia and hoarseness, cough, stridor, shortness of breath, dyspnea, congestion, rhinorrhea, sneezing) followed by dizziness and gastrointestinal tract symptoms (nausea, crampy abdominal pain, vomiting, diarrhea).[14] Ten percent to 30% of patients develop hypotension. Additional cardiovascular effects include syncope, altered mental status, chest pain, and dysrhythmia.[11]

A consensus panel has constructed a definition of anaphylaxis as follows.[11,15] Anaphylaxis is highly likely when any one of the following three criteria are fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, pruritus or flushing, swollen lips/tongue/uvula) AND at least one of the following:
   - Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced peak expiratory flow, hypoxemia)
   - Reduced blood pressure or associated symptoms of end-organ dysfunction (e.g., hypotonia, syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to a likely allergen (minutes to several hours):
   - Involvement of skin/mucosal tissue (as above)
   - Respiratory compromise (as above)
   - Reduced blood pressure or associated symptoms
   - Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced blood pressure after exposure to known allergen (minutes to several hours)

The panel indicated that other presentations may indicate anaphylaxis and that the potential exists for false-positive results.

Anaphylactic reactions generally begin within 30 minutes but almost always within 2 hours of exposure to the inciting allergen. The risk of fatal anaphylaxis is greatest within the first few hours. After apparent recovery, anaphylaxis may recur 6 to 8 hours after antigen exposure. Because of the possibility of these "late-phase" reactions, patients should be observed for at least 12 hours after an anaphylactic reaction. Fatal anaphylaxis most often results from asphyxia due to airway obstruction either at the larynx or within the lungs. Cardiovascular collapse may occur as a result of asphyxia in some cases, whereas in others cases cardiovascular collapse may be the dominant manifestation from the release of mediators within the heart muscles and coronary blood vessels.

SERUM SICKNESS AND SERUM SICKNESS-LIKE DISEASE

Serum sickness is a clinical syndrome resulting from the effects of soluble circulating immune complexes that form under conditions of antigen excess. The reaction commonly results from the use of antisera containing foreign (donor) antigens such as equine serum in the form of antitoxins or antivenoms. The onset of serum sickness is usually 7 to 14 days after antigen administration. The onset may be more rapid with reexposure to the same agent in an individual with prior serum sickness. Fever, malaise, and lymphadenopathy are the most common clinical manifestations. Arthralgias, urticaria, and morbilliform skin eruption also may be present. A milder and more transient form of serum sickness is serum sickness-like disease (SSLD). The predominant feature of SSLD is a cutaneous eruption, either urticarial or maculopapular, that occurs within 5 to 21 days of drug administration.[16] As with serum sickness, the rash is usually preceded by a prodromal phase consisting of fever, malaise, lymphadenopathy, and arthralgias. SSLD has been associated with the administration of ciprofloxacin, bupropion, hydantoins, minocycline, sulfonamides, penicillins, and cephalosporins (especially cefaclor). SSLD is usually self-limiting after discontinuation of the causative agent, but it can sometimes progress to include vasculitis.

DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS)

Previously known by the term *drug hypersensitivity syndrome*, the triad of rash, eosinophilia and internal organ involvement is currently referred to as drug rash with eosinophilia and systemic symptoms (DRESS). Bocquet and colleagues[17] described the following criteria for a diagnosis of DRESS: (1) cutaneous drug eruption (usually a diffuse maculopapular rash accompanied by facial and neck edema); (2) hematologic abnormalities including eosinophilia greater than 1,500 cells/mm^3 (1.5 x 10^9/L) or the presence of atypical lymphocytes; and (3) systemic involvement including adenopathies greater than 2 cm in diameter, hepatitis, interstitial nephritis, interstitial pneumonia or carditis.[17] Both the allopurinol hypersensitivity syndrome and anticonvulsant hypersensitivity syndrome are examples of DRESS.[18] Other drugs associated with DRESS include minocycline, dapsone, lamotrigine and the sulfonamides. The onset of DRESS is typically delayed ranging from 3 to 8 weeks after drug initiation, and there is a high degree of interpatient variability in the targeted organs and the severity of organ involvement.[17,18] The mortality rate associated with DRESS is 10% and it is largely attributed to systemic involvement of the liver, kidneys, or lungs.[18] Following discontinuation of the causative drug, the skin rash resolves and laboratory abnormalities normalize over a period of 4 to 8 weeks. Systemic corticosteroids (0.5–1 mg/kg/day prednisone or steroid equivalent) have been used in the treatment of DRESS based on the severity of organ involvement.

DRUG FEVER

Fever may occur in response to an inflammatory process or develop as a manifestation of a drug reaction. Drug fever occurs in as many as 10% of hospital inpatients.[19] Many drugs have been reported to cause fever, including acyclovir, heparin, methyldopa, procainamide, phenytoin, barbiturates, quinidine, and a variety of antibiotics (e.g., β-lactams, rifampin, sulfonamides, tetracycline, vancomycin). These drugs may affect the central nervous system directly to alter temperature regulation or stimulate the release of endogenous pyrogens (e.g., interleukin 1 and tumor necrosis factor) from white blood cells. Drugs also may cause fever as a result of their pharmacologic effects on tissues, for example, fever resulting from massive tumor cell destruction caused by chemotherapy. However, the mechanism of drug fever remains unknown for agents such as amphotericin B and radiographic contrast agents.

The temperature pattern of drug-induced fever is quite variable and therefore of little help in the diagnosis. It may be low grade and continuous or spiking and intermittent. A temporal relationship between drug administration and occurrence of fever has been noted for some medications. Generally, withdrawal of the causative agent results in prompt defervescence as soon as the drug is eliminated completely. Fever usually recurs on readministration of the causative agent.

DRUG-INDUCED AUTOIMMUNITY

Autoimmune diseases have been associated with drugs and may involve a variety of tissues and organs. A commonly recognized drug-related autoimmune disorder is systemic lupus erythematosus (SLE) induced by infliximab, etanercept, procainamide, hydralazine, quinidine, or isoniazid.[20] Exposure of susceptible persons to these agents appears to alter normal body proteins, RNA, or DNA in such a way as to make these components antigenic, leading to the formation of autoreactive antibodies and cells. Most patients treated with infliximab develop antinuclear antibodies, but only 2% of patients present with SLE symptoms. The most common clinical manifestations include arthralgias, myalgias, and polyarthritis. Facial rash, ulcers, and alopecia occur less frequently. Renal or pulmonary involvement also may occur. These reactions typically develop several months after beginning the drug and generally resolve soon after the drug is discontinued.[21]

Other syndromes believed to involve autoimmune mechanisms include drug-induced hemolytic anemia attributed to methyldopa, interstitial nephritis produced by methicillin, and hepatitis caused by phenytoin and halothane. Interstitial nephritis is characterized by fever, rash, and eosinophilia associated with proteinuria and hematuria. Hepatic damage due to drugs generally is manifested as either hepatocellular necrosis or cholestatic hepatitis. Drug-induced hepatitis has been associated with phenothiazines, sulfonamides, halothane, phenytoin, and isoniazid (see Chapter 45). Hepatocellular destruction is evidenced by elevations in serum transaminases. Hepatomegaly and jaundice sometimes may be evident. Cholestasis may be manifested by jaundice and elevations in serum alkaline phosphatase and sometimes by rash, fever, and eosinophilia.

VASCULITIS

Vasculitis is a clinicopathologic process characterized by inflammation and necrosis of blood vessel walls. The vasculitic process may be limited to the skin, or it may involve multiple organs, including the liver or kidney, joints, or central nervous system. Characteristically, cutaneous vasculitis is manifested by purpuric lesions that vary in size and number. Vasculitis also may be manifested as papules, nodules, ulcerations, or vesiculobullous lesions, generally occurring on the lower extremities but sometimes involving the upper extremities, including the hands. Drugs associated with vasculitis include allopurinol, β-lactam antibiotics, sulfonamides, thiazide diuretics, phenytoin, and vancomycin.

DERMATOLOGIC REACTIONS

A wide variety of dermatologic drug reactions have been reported to have an immunologic basis.[2,22] Cutaneous reactions are the most common manifestations of allergic drug reactions. Although most dermatologic reactions are mild and resolve promptly after discontinuing the drug, some such as SJS and TEN are serious or even life-threatening reactions. Both SJS and TEN are classified as progressive bullous or "blistering" disorders that constitute dermatologic emergencies.[23] They are considered severe variants of erythema multiforme. Similar to erythema multiforme, SJS and TEN are associated with the widespread development of a variety of skin lesions including macules, purpuric lesions and the target iris lesion. The target lesion is discrete, round, and identified by an area of central clearing surrounded by two concentric rings of edema and erythema. Unlike erythema multiforme, SJS and TEN are most commonly drug-induced rather than associated with recurrent herpes simplex viral infection, and they progress to include mucous membrane erosion and epidermal detachment.[23] Mucosal membranes in the mouth, lips, nasal cavity, and conjunctivae are usually involved. As these syndromes progress, the erythematous lesions become more widespread on the face, trunk, and extremities, and many evolve into blisters. Within days after the onset of the lesions, full-thickness epidermal detachment occurs. SJS and TEN are often considered as a continuous spectrum of a disease, with TEN being the most severe form. The extent of epidermal detachment is used to distinguish between SJS and TEN (i.e., <10% detachment of body surface area with SJS; >30% detachment of body surface area with TEN). The term *SJS-TEN overlap* is used to describe cases in which epidermal detachment occurs on 10% to 30% of the body surface area.[23,24] Both SJS and TEN are associated with a number of long-term sequelae including permanent visual impairment, temporary nail loss, cutaneous scarring and irregular pigmentation. Being the more severe form, TEN is also more likely to be complicated by systemic organ involvement including acute kidney failure, neutropenia, and respiratory failure. A severity-of-illness scoring system known as SCORTEN has been developed to predict prognosis in patients with TEN.[25] SCORTEN uses seven independent risk factors based on an assessment within 24 hours of clinical presentation.

Cutaneous adverse reactions were reported to occur in 2.7% of hospitalized patients.[26] TEN is estimated to occur in 0.4 to 1.3 cases per 1 million people per year while SJS has been reported in 1 to 6 cases per 1 million people per year.[27,28] The mortality rates associated with SJS and TEN range from 1% to 5% and 10% to 70%, respectively.[28] Table 97–2 lists drugs and agents associated most commonly with cutaneous reactions.[22] In general, antimicrobials are implicated most frequently as the cause of cutaneous events with reaction rates ranging from 1% to 8%. The most likely offenders of SJS and TEN, determined in case-control studies, are the sulfonamides, particularly trimethoprim-sulfamethoxazole.[29] Other major offenders of SJS and TEN identified in these studies are allopurinol, the aminopenicillins, carbamazepine, chlormezanone, cephalosporins, the imidazole antifungals, lamotrigine, nevirapine, the oxicam NSAIDs, phenytoin, quinolones, and the tetracyclines.[29]

RESPIRATORY REACTIONS

Drugs may produce upper or lower respiratory tract reactions, including rhinitis and asthma. Respiratory tract manifestations may result from direct injury to the airways or may occur as a component of a systemic reaction (e.g., anaphylaxis). Asthma may be induced by aspirin and other NSAIDs or by sulfites used as preservatives in foods and medications. Other pulmonary drug reactions believed to be immunologic include acute infiltrative and chronic fibrotic pulmonary reactions. The latter is often caused by antineoplastic agents such as bleomycin. For a more detailed discussion of drug-induced pulmonary disease, see Chapter 36.

TABLE 97-2 Top 10 Drugs or Agents Reported to Cause Skin Reactions

	Reactions per 1,000 Recipients
Amoxicillin	51.4
Trimethoprim–sulfamethoxazole	33.8
Ampicillin	33.2
Iopodate	27.8
Blood	21.6
Cephalosporins	21.1
Erythromycin	20.4
Dihydralazine hydrochloride	19.1
Penicillin G	18.5
Cyanocobalamin	17.9

Data from Roujeau JC, Stern RS. N Engl J Med 1994;331:1272–1285.

HEMATOLOGIC REACTIONS

Most formed elements and soluble components of the hematopoietic system may be affected by immunologic drug reactions. Eosinophilia is a common manifestation of drug hypersensitivity and may be the only presenting sign. Hemolytic anemia may result from hypersensitivity to drugs. Other hematologic reactions include thrombocytopenia, granulocytopenia, and agranulocytosis. For a detailed discussion of hematologic drug reactions, see Chapter 112.

FACTORS RELATED TO THE OCCURRENCE OR SEVERITY OF ALLERGIC DRUG REACTIONS

4 Among the factors that influence the likelihood of allergic drug reactions are the degree to which the drug and its metabolites bind covalently to human proteins, how the drug is metabolized, whether the drug contains proteins of nonhuman origin (e.g., chimeric monoclonal antibodies, streptokinase) or antigenic excipients (e.g., peanut oil, FD&C dyes, sulfites, soybean emulsion), the route of exposure, and the sensitivity of the individual as determined by genetics, and environmental factors. Hypersensitivity can occur with any dose of a drug, but sensitization is more likely to occur with continuous dosing rather than single dosing. Once a patient has become sensitized, the severity of a reaction is often determined by the dose and the duration of exposure. The route of administration may also influence drug sensitivity. The topical route of drug administration appears to be the most likely to sensitize and predispose to drug reactions. The oral route is the safest, and the parenteral route is the most hazardous for administration of drugs in sensitive individuals. Relatively few cases of immediate hypersensitivity-associated deaths with oral β-lactam antimicrobials have been reported.

Individual host factors are important in determining drug sensitivity. A genetic predisposition for some types of allergic reactions has been identified. The presence of genetically determined human leukocytic antigen (HLA) alleles increases susceptibility to a number of drug hypersensitivity syndromes. In patients infected with the human immunodeficiency virus (HIV), hypersensitivity to abacavir has been associated with the presence of *HLA-B*5701*.[30] Severe immune-mediated cutaneous reactions to allopurinol including SJS and TEN have been associated with the presence of *HLA-B*5801* in Han Chinese.[31] In this same patient population, the presence of *HLA-B*1502* increases the risk of SJS and TEN with carbamazepine, phenytoin and fosphenytion.[32] Genetic factors can also influence the metabolic deactivation of drugs via phase 1 and 2 metabolism. For example, slow acetylators of procainamide and hydralazine are at increased risk for SLE. Genes also encode for the type of T cell receptor and the specific cytokines involved in the signaling of allergic drug reactions.

Drug allergies appear to develop with equal frequency in atopic and nonatopic individuals. In addition, patients with a history of drug allergy appear to be at increased risk for adverse reactions to other pharmacologic agents.[3] Age seems to be related to the risk of allergic reactions, as they occur less frequently in children. This may be related to immaturity of the immune system or decreased exposure. The presence of some concurrent diseases, particularly viral infections, predisposes to drug reactions. Examples include the higher rate of morbilliform rash when ampicillin is administered to patients with infectious mononucleosis, the higher rate of reactions to trimethoprim-sulfamethoxazole in HIV-infected patients and the relationship between infection with human herpes-virus 6 (HHV-6) and the development of drug rash with eosinophilia and systemic symptoms (DRESS).

DRUGS COMMONLY CAUSING ALLERGIC OR ALLERGIC-LIKE DRUG REACTIONS

β-LACTAM ANTIMICROBIALS

Allergy to β-lactam antibiotics is commonly reported by patients in healthcare settings.[33] Allergic reactions to penicillin occur in 0.7% to 8% of treatment courses but was as high as 15% in one retrospective report of hospitalized patients treated with penicillin.[34,35] Although most patients reporting penicillin allergy do not have allergy, a reported history is associated with a higher likelihood of positive skin test reactivity.[36] Only 10% to 20% of patients reporting penicillin allergy are found to be allergic by skin testing.[36] Patients with a history of immediate penicillin allergy who have a negative penicillin skin test are unlikely to react on subsequent courses of penicillins.[37]

The most common reactions to penicillin include urticaria, pruritus, and angioedema. All four of the major types of hypersensitivity reactions have been reported with penicillin, as well as some reactions that do not fit into these categories. A wide variety of idiopathic reactions occur, such as maculopapular eruptions, eosinophilia, SJS, and exfoliative dermatitis. Cutaneous reactions can occur in up to 4.4% of treatment courses of penicillin[38] and in up to 8% with aminopenicillins.[39] The incidence of ampicillin rash is close to 100% in patients with viral infections such as infectious mononucleosis.[40]

Some aspects of the mechanism of penicillin immunogenicity have been determined. Because benzylpenicillin is a relatively small molecule (356 Da), it must combine with macromolecules (presumably proteins) to elicit an immune response. Penicillin is rapidly hydrolyzed to a number of reactive metabolites that have the ability to covalently link to proteins. Of these metabolites, 95% is in the form of benzylpenicilloyl that binds covalently to the lysine residues of proteins such as albumin through an amide linkage involving the β-lactam ring (Fig. 97–2). This penicilloyl–protein conjugate is referred to as the *major antigenic determinant*. The other penicillin metabolites such as penilloate and penicilloate bind in lesser quantities to proteins. These are referred to as *minor antigenic determinants*. The terms *major* and *minor* refer to the relative proportions of these conjugates that are formed and not to the clinical severity of the reactions generated. Immediate hypersensitivity reactions may be mediated by IgE for both minor and major determinants. In fact, the minor antigenic determinants are more likely to cause life-threatening anaphylactic reactions.

In addition to the major and minor determinants, unique side chain determinants may mediate allergy to some penicillins. Both the aminopenicillins and piperacillin may cause hypersensitivity reactions via unique side chains on their structures.[41,42] Therefore, a patient may exhibit hypersensitivity to amoxicillin or piperacillin via a side chain determinant while exhibiting no reactivity to other penicillins. Careful history taking is needed to identify patients with high likelihood of side-chain specific reactions. Skin testing with dilute concentrations of amoxicillin, ampicillin, and piperacillin has been used to aid in the determination of side-chain specific reactions.[43–45]

Patients who are allergic to penicillins also may be sensitive to other β-lactams.[46,47] The exact incidence of cross-reactivity between cephalosporins and penicillins is not known but is believed to be low.[45,46] The risk was originally reported as 10% to 15% in the 1970s when cephalosporins were contaminated with trace amounts of penicillin. Current estimates of the cross-reactive risk between penicillin and the first- and second-generation cephalosporins are 5% to 7.5% and as low as 1% between penicillin and the third- and fourth-generation cephalosporins.[48] One percent to 8% of patients

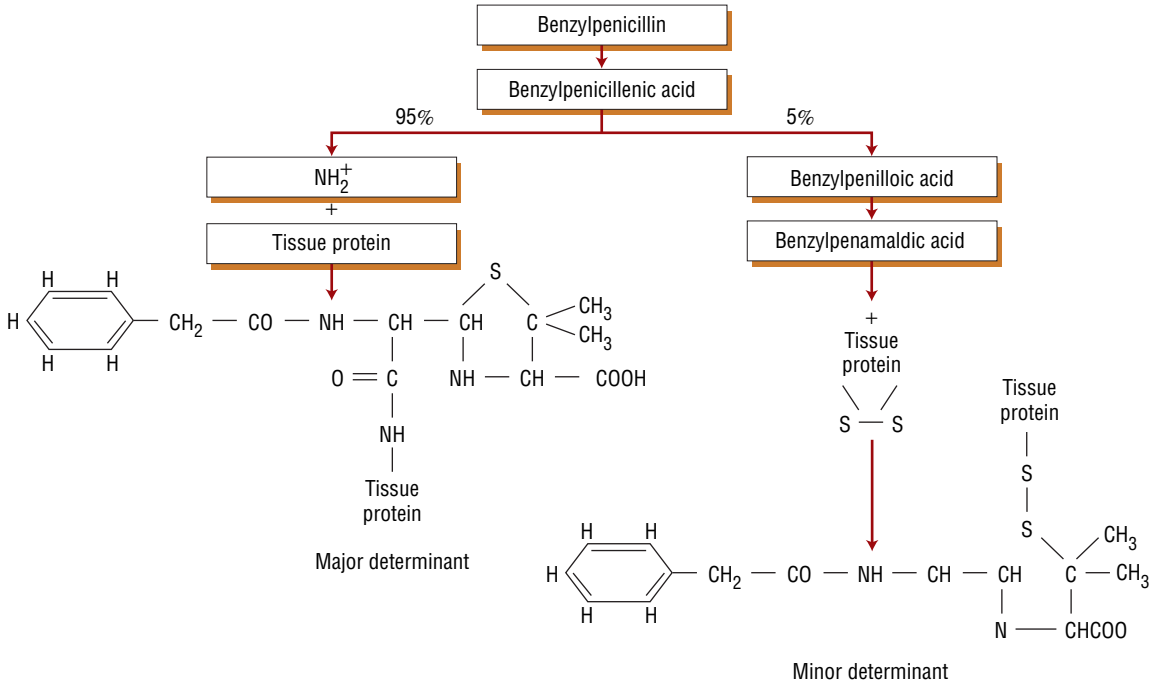

FIGURE 97-2. Formation of a benzylpenicilloyl hapten–protein complex.

with penicillin-specific IgE may develop an immediate-type hypersensitivity reaction to cephalosporins.[49] In contrast, patients with reported penicillin allergy and negative skin test are at no greater risk.[48]

5 Cephalosporins should be avoided in patients with a history of hives or other immediate hypersensitivity reactions from penicillin, although some studies have suggested there is little risk of an allergic response to a cephalosporin even in a person with a positive skin test to penicillin. Based on the results of one meta-analysis, patients with penicillin allergy have the highest risk of cross-reactivity with the first generation cephalosporins (odds ratio [OR], 4.79; 95% confidence interval [CI], 3.71–6.17).[50] The odds of reacting to a second- and third-generation cephalosporin were 1.13 (95% CI, 0.61–2.12) and 0.45 (95% CI, 0.18–1.13), respectively.[50] The higher rate of cross-reactivity between penicillin and the first generation cephalosporins has been attributed to similarities in the R1 side chains of these agents.[45,46] The R1 side chain is connected to the opened β-lactam ring, thereby influencing the antigenicity of these agents. When assessing the potential for cross-reactivity between penicillins and cephalosporins, clinicians should evaluate the similarities in the R1 side chains of the agents.[45,46,50,51] Table 97–3 provides a list of penicillins and cephalosporins having similar side chains in the R1 position.

Cephalosporins can induce immune responses mediated by the core β-lactam structure or via unique side chain determinants.[46,48,50] In a patient with a cephalosporin allergy, skin testing with the major and minor determinants of penicillin can be used to identify the likelihood of reactivity to the core β-lactam ring. The risk of cross-reactivity between cephalosporins is considered to be higher than that between the penicillins and cephalosporins.[48] Cross-reactions may occur through identical R1 side chains. Of note, ceftazidime shares a common side chain with aztreonam.

The actual risk of a cross-reaction between the penicillins and the carbapenems appears to be much lower than originally described. The initial estimate of the cross-reactive risk was 47.4%, but current estimates range from 0.9% to 11%.[47] The initial estimate was based on the results of skin testing with penicillin and nonstandardized carbapenem reagents. A number of retrospective studies reporting variable rates of cross-reactivity relied on self-reported histories as confirmation of penicillin allergy. Three recently published prospective studies used both skin testing methods and carbapenem challenge dosing to assess cross-reactive risk. In one of these studies, only 1 of 112 patients with skin test-confirmed penicillin allergy demonstrated a positive skin test to imipenem.[52] Challenge dosing with imipenem to a final dose of 500 mg was subsequently performed in 110 patients with negative imipenem skin tests; none of the 110 patients had a reaction. Results of two additional prospective studies, one of which was performed in children ages 3 to 14 years, suggest a low risk of cross-reactivity between penicillin and meropenem.[53,54] In both studies, only one patient with skin-test positivity to penicillin had a positive skin test to meropenem. Graded challenge dosing with meropenem was tolerated in 100% of the skin-test negative patients in both

studies. It is important to note that none of the skin-test negative patients were subsequently treated with full therapeutic regimens of the carbapenem. However, the high level of tolerability to challenge dosing suggests a low rate of cross-reactivity in skin-test negative patients. Based on these results, the routine practice of avoiding carbapenem use in patients with history of penicillin allergy should be reconsidered.[47]

Of the monobactams, aztreonam only weakly cross-reacts with penicillin and can be administered safely to most patients who are penicillin allergic.[47]

RADIOCONTRAST MEDIA

6 Radiocontrast agents frequently cause reactions categorized as immediate (in ≤1 hour) or non-immediate (in 1–10 days) via both IgE-mediated and non-IgE–mediated mechanisms.[55] The frequency and severity of these reactions are influenced by the type of radiocontrast agent (ionic versus nonionic), and patient-specific factors such as history of atopy, asthma, or prior reaction to a radiocontrast agent. From <1% to >3% of patients receiving nonionic contrast media experienced an adverse reaction, with reports as high as 12.7% for mild reactions.[55,56] Delayed skin reactions, usually presenting as maculopapular exanthems, occur in 1% to 3% of patients over 5 to 7 days. Severe, immediate anaphylactic reactions occur in 0.01% to 0.04% of patients.[39] In addition, radiocontrast agents may cause dose-dependent toxic reactions that can produce renal impairment, cardiovascular effects, and arrhythmias.[57] The older, high-osmolar ionic agents that are now used less commonly have a greater frequency of reactions compared with the newer, low-osmolar agents.[55] The mechanism of reactions to radiocontrast agents is not clearly understood. Histamine release and mast cell triggering have been documented in severe immediate reactions, suggesting an IgE-mediated mechanism.[58] The older, high-osmolar radiocontrast agents can activate mast cells, basophils and the complement system directly (IgE-independent mechanism), resulting in the release of inflammatory mediators. The delayed-onset maculopapular rash appears to be T-cell mediated. The low-osmolar nonionic contrast agents appear to cause fewer anaphylactoid reactions.

The risk of anaphylactoid reactions to radiocontrast media is greater in women and in patients with a history of atopy or asthma.[55] Other recognized risk factors include a history of previous reaction, severe drug allergies, cardiac disease, and treatment with β-blockers.[56] Despite a common misconception, seafood allergy or iodine allergy does not predispose to radiocontrast media reactions. Neither skin tests nor oral tests are useful for predicting reactions to these agents. Although some regimens have been recommended to prevent the recurrence of immediate events in patients who have experienced reactions previously, the value of these preventive regimens has not been proven and their use remains controversial.[55,59] A commonly recommended regimen in high risk patients is oral prednisone (50 mg) 13, 7, and 1 hours before exposure with 50 mg of diphenhydramine given orally or intramuscularly 1 hour before exposure to prevent immediate reactions.[60] Ephedrine 25 mg orally has also been recommended 1 hour before the radiocontrast study as a component of the pretreatment regimen; however, ephedrine should not be used if the patient has history of unstable angina, hypertension or arrhythmia.[60] Other studies have examined the use of H_1- and H_2- antihistamines, clemastine, or cimetidine, respectively.[59]

INSULIN

Insulin is capable of producing allergic reactions through a variety of immunologic mechanisms. A protein molecule, insulin is a complete antigen. Allergic reactions have been reported with beef, pork, and recombinant human insulin, although the frequency of reactions with human insulin appears low. Reactions to insulin may involve the insulin molecule itself or other substances that have been added to insulin (e.g., protamine). Most patients have anti-insulin IgG antibodies after a few months of therapy.

Insulin reactions may be limited to the site of injection, or they may produce systemic reactions. Local reactions present most often as a wheal and flare at the injection site and may occur immediately after injection or up to 8 to 12 hours later. Generally, these reactions are mild, do not require treatment, and resolve with continued insulin administration. If a patient does not tolerate the local reaction well, antihistamines may be given or a different insulin source (or product of higher purity) may be substituted. Rarely, systemic reactions to insulin (e.g., urticaria or anaphylaxis) occur. IgE-mediated reactions to insulin allergy appear to be declining with greater use of human insulins.[61] Skin testing with various products can aid in selecting the type of insulin least likely to cause a systemic reaction. Human insulin appears to be least allergenic but occasionally may cause reactions. In some patients, insulin desensitization may be indicated.

ASPIRIN AND NONSTEROIDAL ANTIINFLAMMATORY DRUGS

7 Aspirin and other NSAIDs can produce eight general types of reactions, four of which are related to cyclooxygenase inhibition.[62,63] These reactions can involve asthma and rhinitis, urticaria/angioedema, anaphylaxis and anaphylactoid reactions, aseptic meningitis, or pneumonitis. The two most prevalent aspirin sensitivity reactions are respiratory (asthma, rhinorrhea) and urticaria/angioedema. Approximately 9% to 20% of asthmatics are sensitive to aspirin and other NSAIDs.[62,64]

The rhinosinusitis/asthma syndrome typically develops in middle-aged patients who are nonatopic and have no history of aspirin intolerance. Women are 2.5 times more likely to develop aspirin-induced asthma than men.[65] It usually progresses from rhinitis to sinusitis with nasal polyps and steroid-dependent asthma. It is uncommon in children and young adults. However, children with asthma may be aspirin sensitive. Aspirin-sensitive asthma appears to be an inherited disorder characterized by overexpression of LTC_4 synthase in airways.[66] In aspirin-sensitive asthmatics, administration of aspirin and NSAIDs may provoke severe and sometimes fatal asthmatic attacks. The mechanism of aspirin sensitivity is not completely understood.

One suspected mechanism of aspirin and NSAID sensitivity is cyclooxygenase-1 blockade, which may facilitate depletion of prostaglandin E2 (PGE2) and production of alternative arachidonic acid metabolites (e.g., LTs).[62] PGE2 prevents mast cell degranulation, whereas LTs cause bronchoconstriction and increased mucus production. Increased LT production may also explain the development of angioedema and urticaria. This proported mechanism is supported by the observed correlation between the degree of cyclooxygenase-1 blockade and the risk of a sensitivity reaction; thus, agents such as acetaminophen, which minimally block cyclooxygenase 1, rarely cause reactions. Additional support is found in the clinical observation that LT-modifying drugs can reduce the severity of aspirin-induced asthma and urticaria.[62] It is also possible that aspirin and NSAIDs stimulate mast cells directly to release inflammatory mediators. Subjects with aspirin-induced asthma also have a marked increase in airway responsiveness to LTs.[67] Aspirin and the cyclooxygenase-2–selective inhibitors celecoxib and rofecoxib do not appear to be cross-reactive.[68–70]

In patients with aspirin sensitivity (asthma or urticaria), an oral challenge or provocation test can be performed to diagnose the

condition. A number of different protocols to detect aspirin or NSAID sensitivity have been recommended, but the risk for anaphylaxis cannot be reliably predicted.[62,65] The challenge should be performed with great caution in a hospital setting with resuscitation equipment at hand. For patients with aspirin-induced asthma, desensitization is recommended. Aspirin desensitization has been shown to improve asthma symptom scores and lead to reductions in maintenance steroid doses. If desensitization is not performed, patients with aspirin sensitivity must avoid aspirin and the nonselective NSAIDs as the major preventive measure.

Aspirin and individual NSAIDs (e.g., ibuprofen, sulindac) can also cause IgE-mediated hypersensitivity. These reactions occur on re-exposure to the drug and may present as urticaria, bronchospasm or anaphylaxis with or without hypotension. A careful and complete allergy history may suggest true hypersensitivity to aspirin or an isolated NSAID. Such patients should be advised to avoid the specific NSAID and any structurally similar NSAIDs (e.g., all propionic acid derivatives, all indole acetic acid derivatives) because of the risk of cross-reactivity.

NSAIDs have been associated with pulmonary infiltrates and eosinophilia syndrome. Pulmonary infiltrates and eosinophilia syndrome is associated with fever, cough, dyspnea, infiltrates on chest roentgenogram, and a peripheral eosinophilia that develop 2 to 6 weeks after initiating treatment. Pulmonary infiltrates and eosinophilia syndrome occurs more frequently for naproxen compared with other NSAIDs and is noted to resolve rapidly after discontinuation of the offending agent.[71]

SULFONAMIDES

Sulfonamide drugs containing the sulfa (SO_2NH_2) moiety include antibiotics, thiazide and loop diuretics, oral hypoglycemics, and carbonic anhydrase inhibitors. Allergic reactions have been reported in 4.8% of 20,226 patients who received a sulfonamide antibiotic and in 2% of patients who received a nonantibiotic sulfonamide.[72] Although immediate IgE-mediated reactions such as anaphylaxis can occur, sulfonamides typically cause delayed cutaneous reactions, often beginning with fever and then followed by a rash (e.g., maculopapular or morbilliform eruptions). Infrequently, a seemingly benign maculopapular rash may progress to a mucocutaneous syndrome (e.g., SJS/toxic epidermal necrolysis).[1] Other reactions to sulfonamides may include hepatic, renal, or hematologic complications, which may be fatal. Immune-mediated sulfonamide reactions depend on the production of reactive metabolites in the liver.[73] Trimethoprim-sulfamethoxazole, considered the most highly reactive sulfonamide, contains an arylamine in the N4 position of its chemical structure allowing for the drug's metabolism to two highly reactive metabolites, a hydroxylamine and a nitroso-sulfonamide.[73,74] Structural differences between the sulfonamides antibiotics and non-antibiotics may influence the metabolic conversion and resultant reactivity of these compounds. Slow acetylator phenotype may also increase the risk for these reactions.[4]

8 Cross-reactivity between sulfonamide antibiotics and non-antibiotics appears to be minimal, with cross-reactivity characterized as "highly unlikely."[75] In one study, about 10% of patients with history of allergy to an antibiotic sulfonamide subsequently reacted to a non-antibiotic sulfonamide (e.g., acetazolamide, loop diuretic, sulfonylurea, thiazide).[72] This low rate of cross-reactivity has been attributed in part to differences in the chemical structures of the antibiotic and non-antibiotic sulfonamides. The occurrence of allergic reactions after receipt of non-antibiotic sulfonamides has also been attributed to a predisposition to allergic reactions in the affected individuals rather than cross-reactivity with sulfonamide antibiotics.[72] In fact, in one study, cross-reactivity between sulfonamide antibiotics and penicillin was higher than that between the antibiotic and nonantibiotic sulfonamides.[72]

Trimethoprim–sulfamethoxazole is used frequently for preventive or active treatment of *Pneumocystis jiroveci* pneumonia in patients with AIDS. Adverse reactions to trimethoprim–sulfamethoxazole occur much more frequently in human immunodeficiency virus (HIV)-positive patients.[76,77] Adverse effects to trimethoprim–sulfamethoxazole occur in 50% to 80% of AIDS patients compared with 10% of other immunocompromised patients.[77] Trimethoprim–sulfamethoxazole was associated with an adverse event rate of 26.3 per 100 person-years and hypersensitivity events at 22 per 100 person-years. Although reactions may include angioedema, SJS, and thrombocytopenia, most reactions to trimethoprim–sulfamethoxazole in HIV-infected patients are delayed and present as diffuse maculopapular rash with or without fever. The mechanism by which these allergic or allergic-like reactions occur in HIV-infected patients is unclear. It is unlikely that these reactions are IgG or IgE-mediated.[74,78] Theories support alterations in drug metabolism due to glutathione deficiency, a direct toxic or immunologic effect of the sulfonamide metabolites on body tissues, and increased expression of major histocompatibility complex proteins with increased recognition of the drug antigen by CD4 and CD8 cells.[74,78] The adverse event rate has been related to higher $CD4^+$ T cell count >20 cells/mm^3 (>20 × 10^6/L), CD4/CD8 ratio <0.10 and treatment for less than 14 days.[77]

PHARMACEUTICAL EXCIPIENTS AND ADDITIVES

Pharmaceutical products contain a number of "inert" additives (e.g., dyes, fillers, buffers, and stabilizers) in addition to the therapeutic ingredients. These additives are not always inert and may cause adverse effects, including allergic reactions.

The azo dye tartrazine (FD&C Yellow No. 5) is associated with anaphylactoid reactions, acute bronchospasm, urticaria, rhinitis, and contact dermatitis.[79,80] Although the immunologic mechanisms are unclear, approximately 10% of aspirin-sensitive asthmatics are also intolerant to tartrazine,[81] suggesting a role for tartrazine as a cyclooxygenase inhibitor. As little as 0.85 mcg or as much as 25 mg tartrazine has provoked positive responses.[81]

Sulfites (including sulfur dioxide, sodium sulfite, sodium and potassium bisulfite, and sodium and potassium metabisulfite) are used commonly as antioxidants in pharmaceutical products and some foods. Many cases of adverse reactions associated with ingestion of sulfites (usually in foods) have been reported to the U.S. Food and Drug Administration (FDA),[82] including wheezing, dyspnea, chest tightness, urticaria, angioedema, flushing, weakness, nausea, anaphylaxis, and death.

IgE-mediated and nonimmunologic sulfite hypersensitivity has been demonstrated in children with a history of chronic asthma. Adverse reactions to sulfite-preserved injectables, such as gentamicin, metoclopramide, lidocaine, and doxycycline, have been reported. In contrast to reactions caused by foods, these reactions do not occur more frequently in steroid-dependent asthmatics and do not always coincide with a positive oral sulfite challenge.[83] Blunted bronchodilation may be observed in asthmatics following inhalation of sulfite-containing nebulizer solutions. Although many nebulizer solutions contain sulfites, metered-dose inhalers do not. Many aqueous epinephrine products also contain sulfites. The FDA labeling states that in emergency situations when sulfite-free preparations are not available, sulfite-containing epinephrine should not be withheld from a sulfite-intolerant individual because small subcutaneous doses of sulfites usually are well tolerated. However, an increased risk of anaphylaxis exists after subcutaneous injection in rare patients with a positive oral challenge to 5 to 10 mg sulfite.

Parabens (including methyl-, ethyl-, propyl-, and butylparaben) are used widely in pharmaceutical products as a biocidal agent. Most allergic reactions to parabens are observed after topical exposure.[84] Delayed hypersensitivity contact dermatitis occurs more often in individuals with preexisting dermatitis.[81] Immediate hypersensitivity after parenteral administration is rare. Although these agents are chemically related to benzoic acid and *p*-aminobenzoic acid, the evidence for cross-sensitivity is lacking.[81]

CANCER CHEMOTHERAPY AGENTS

Chemotherapy agents are implicated in hypersensitivity reactions in 5% to 15% of patients who receive them.[85] Up to 65% of patients receiving L-asparaginase experience immediate hypersensitivity reactions such as urticaria and anaphylaxis.[86]

The combination regimen of paclitaxel (or docetaxel) and carboplatin frequently is responsible for producing hypersensitivity reactions. Each agent precipitates a distinct reaction, allowing for differentiation between causative factors. Hypersensitivity reactions have been observed with paclitaxel and docetaxel as frequently as 34% of patients.[1,87,88] The reaction, typically occurring shortly after initiation of the first dose, is due to Cremophor EL, the polyoxyethylated castor oil vehicle for paclitaxel. Severe reactions are characterized by dyspnea, bronchospasm, urticaria, and hypotension. Minor reactions include flushing and rashes. In patients receiving a 3-hour infusion, the incidence of severe reactions is reduced to 1.3%, and the incidence of minor reactions is 42%.[89] To reduce the risk of hypersensitivity reaction, patients are routinely premedicated with corticosteroids and H_1- and H_2-receptor antagonists. A protein-bound formulation of paclitaxel (Abraxane) is available that avoids most of the hypersensitivity reactions.

Carboplatin hypersensitivity develops after six or more courses of carboplatin or its parent compound cisplatin.[90] Reactions typically develop shortly after completing the infusion or up to 3 days after therapy.[91] Symptoms of severe reaction include tachycardia, dyspnea, facial swelling, rigors, and hypotension. Mild reactions include itching, erythema, and facial flushing. Both skin testing with carboplatin and desensitization have been shown to be effective.[92,93]

Oxaliplatin hypersensitivity has been reported in as many as 12% of patients. Symptoms range from facial flushing to dyspnea. Management strategies include decreasing the rate of infusion and administration of corticosteroids and H_1- and H_2-receptor antagonists.[94] Desensitization has been successful in patients desiring to continue treatment after experiencing a hypersensitivity reaction.[95,96]

ANTICONVULSANTS

Many anticonvulsant drugs produce a variety of hypersensitivity reactions and pseudoallergic reactions. Drugs such as phenytoin, phenobarbital, carbamazepine, and lamotrigine can cause an "anti-convulsant hypersensitivity syndrome" characterized by fever, rash, lymphadenopathy, and internal organ involvement. Eosinophilia is frequently present and many reactions meet the definition of DRESS. Onset usually occurs several weeks into therapy.[97] In some cases, morbilliform rash develops into exfoliative dermatitis. The risk of cross-reactivity between the aromatic anticonvulsants (e.g., carbamazepine, phenobarbital, and phenytoin) ranges from 40% to 80%.[98] Oxcarbazepine, the 10-keto derivative of carbamazepine, has exhibited both in vitro and in vivo cross-reactivity with carbamazepine. A genetic marker for severe reactions to carbamazepine, phenytoin and fosphenytoin is the presence of the *HLA-B*1502* allele.[32] This allele is found in 10% to 15% of patients from China, Thailand, Malaysia, Indonesia, the Philippines, and Taiwan. Concomitant use of valproate with lamotrigine significantly increases the risk of hypersensitivity as a result of reduced lamotrigine metabolism, leading to a prolonged elimination half-life.[99]

BIOLOGICS

Biologic agents (e.g., monoclonal antibodies, fusion proteins, recombinant proteins) are derived from living sources such as yeast, bacteria, animal cells, or mammalian cells.[100] Unlike nonbiologic agents, these large proteins can serve as complete antigens. Examples include recombinant insulin, erythropoietin, interferon-β, human growth hormone, infliximab, rituximab, and omalizumab. Immunologic reactions to these agents range from minor infusion or injection-site reactions to anaphylaxis. Depending on the agent, reactions can occur on first or subsequent exposure and the timing may be within 4 hours of drug administration or up to 14 days after an infusion.[100]

Factors influencing the antigenicity of biologic agents are patient-specific (e.g., atopy, congenital protein deficiency), production related (e.g., presence of contaminants or stabilizing agents, degree of protein glycosylation, presence of nonhuman protein sequences, storage temperature), and administration-related (e.g., route of administration, frequency of use, concurrent inmmunosuppressant use).[100] Of the monoclonal antibodies, reactions are most frequently observed with the murine-derived agents (0% human) and chimeric agents (75% human) as opposed to the humanized (>90% human) and human (100% human) agents. Some immune reactions to biologic agents result from the development of neutralizing antibodies that can prevent the protein from exerting its intended effect. Neutralizing antibodies have been shown to mediate reactions to interferon-β_{1b} and β_{1a}, infliximab, natalizumab, recombinant factor VIII, and recombinant factor IX.[100] Anti-infliximab antibodies, which occur in up to 60% of treated patients, are associated with higher frequency of infusion reactions and decreased therapeutic effect.[101] Concomitant administration of immunosuppressive agents such as prednisone or low dose methotrexate has been shown to decrease the incidence of antibody formation to infliximab.[100,101]

Delayed onset anaphylaxis, ranging from minutes to days post-injection, has been reported with omalizumab, a humanized monoclonal antibody targeted against IgE.[102,103] Omalizumab-treated patients require extended observation post-injection and are advised to carry an epinephrine auto-injector during and for 24 hours after drug administration.[102] Risk factors for this adverse event have not been identified. Inclusion of polysorbate 80 as a stabilizing agent in the formulation, and an alteration in the protein sequence via glycosylation, may influence the immunogenicity of omalizumab.[103]

Management of allergic or allergic-like reactions to biologic agents varies based on the culprit agent and the severity and nature of the reaction. Immediate management with epinephrine and permanent discontinuation of the drug may be warranted (e.g., omalizumab-induced anaphylaxis). Depending on the biologic agent, reactions may be managed by decreasing the infusion rate or lessened by pretreating with antihistamines and/or corticosteroids or administering concomitant steroid therapy.

TREATMENT

Allergic Reactions

9 The basic principles for management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or agent when possible, (b) treatment of the adverse clinical signs and symptoms, and (c) substitution, if necessary, of another agent.[104]

TABLE 97-4 Treatment of Anaphylaxis

1. Place patient in recumbent position and elevate lower extremities.
2. Monitor vital signs frequently (every 2–5 minutes) and stay with the patient.
3. Administer epinephrine 1:1,000 into nonoccluded site: (adults: 0.01 mL/kg up to a maximum of 0.2–0.5 mL every 5 minutes as needed, children: 0.01 mL/kg up to a maximum dose of 0.2–0.5 mL) subcutaneously or intramuscularly. If necessary, repeat every 5 minutes, up to 2 doses, then every 4 hours as needed.
4. Administer oxygen, usually 8–10 L/min; however, lower concentrations may be appropriate for patients with chronic obstructive pulmonary disease. Maintain airway with oropharyngeal airway device.
5. Administer the antihistamine diphenhydramine (Benadryl, adults 25–50 mg; children 1–2 mg/kg) usually given parenterally. Apply tourniquet proximal to site of antigen injection; remove every 10–15 minutes. Consider ranitidine 1 mg/kg diluted in D5W to a total volume of 20 mL given IV over 5 minutes.
6. If anaphylaxis is caused by an injection, administer aqueous epinephrine 1:1,000 into site of antigen injection; 0.15–0.3 mL into the injection site.
7. Treat hypotension with IV fluids or colloid replacement, and consider use of a vasopressor such as dopamine.
8. Treat bronchospasm resistant to epinephrine with nebulized albuterol 2.5–5 mg in 3 mL saline every 20 minutes for 3 doses; in children, 0.15 mg/kg via nebulizer every 20 minutes for 3 doses.
9. Give hydrocortisone, 5 mg/kg, or approximately 250 mg IV (prednisone 20 mg orally can be given in mild cases) to reduce the risk of recurring or protracted anaphylaxis. These doses can be repeated every six hours as required.
10. In refractory cases not responding to epinephrine because a β-adrenergic blocker is complicating management, glucagon 1 mg IV as a bolus may be useful. A continuous infusion of glucagon, 1–5 mg/h, may be given if required.

ANAPHYLAXIS

Anaphylaxis requires prompt treatment to minimize the risk of serious morbidity or death. On presentation, attention should be given first to stopping the likely offending agent, if possible, and restoring respiratory and cardiovascular function. A protocol for treatment of anaphylaxis is presented in Table 97–4. Epinephrine is administered as primary treatment to counteract bronchoconstriction and vasodilation. Epinephrine should be administered intramuscularly in the lateral aspect of the thigh.[105] If blood pressure is not restored by epinephrine, crystalloid intravenous fluids should be administered to restore intravascular volume. Typically, 1 L of 0.9% sodium chloride or lactated Ringer solution is administered over 10 to 15 minutes. This can be repeated if the patient is still believed to be volume depleted. A maintenance intravenous fluid then is initiated. Intravenous fluids should be given early in the course of treatment in an attempt to prevent shock. An immediate priority is to establish and maintain an airway by the use of endotracheal intubation if necessary. When a patient with anaphylaxis is hypotensive, vasopressors may be needed in addition to crystalloids. Norepinephrine is the vasoconstrictor agent of choice for treatment of anaphylactic shock, although dopamine also may be useful. Patients in shock should remain supine with raised legs.[37]

Other agents may be required for treatment of anaphylactic reactions. Corticosteroids (hydrocortisone sodium succinate intravenously) can reduce the risk of late-phase reactions. In patients treated chronically with β-blockers, glucagon should be considered because its inotropic and chronotropic effects do not rely on β-receptor responsiveness.[60] Histamine (H_1) receptor blockers (e.g., diphenhydramine) can be administered to reduce some of the symptoms associated with anaphylaxis, but these agents are not effective as primary therapy. The combination of diphenhydramine and an H_2 receptor blocker (e.g., ranitidine) has been shown to be superior to diphenhydramine alone in the treatment of anaphylaxis.[60]

SKIN TESTING AND DRUG PROVOCATION TESTING

Identification of patients at high risk for allergic drug reactions requires careful history-taking with attention to the specific agent to which the patient reacted, a complete description of the reaction, and the time since last exposure to the culprit drug. The importance of accurate and complete history taking cannot be overstated. Although skin and oral provocation testing are used to assess reactive risk to some drugs, many of the testing procedures have not been validated. A drug provocation test, or DPT, involves the controlled administration of a drug for the purpose of diagnosing an immune response. DPTs can be used to evaluate sensitivity to aspirin.[106,107] When available, skin testing should be performed prior to a DPT due to the lesser risks incurred to the patient. For some drugs, skin testing can reliably demonstrate the presence of drug-specific IgE and predict a relatively high risk of immediate hypersensitivity reactions. Reliable skin test reagents are not available for most culprit drugs. Moreover, skin testing should not be performed in patients with history of severe mucocutaneous reactions (e.g., SJS, TEN) or other non-immediate reactions (e.g., serum sickness, vasculitis, hepatitis).

Skin testing can reduce the uncertainty of penicillin sensitivity and should be performed in all patients who have a history of an immediate allergy and require treatment with a β-lactam antibiotic. Penicillin skin testing in advance of need for penicillin treatment in patients with a history of penicillin allergy does not appear to induce sensitization.[108] Testing for the major penicillin determinant is accomplished with penicilloyl-polylysine (PPL; Pre-Pen), but this product is not currently available in the United States. If this agent is used alone, patients reacting only to minor determinants will be missed. At present, there is also no commercially available product that can be used to test for most of the minor determinants. Benzylpenicillin (at a concentration of 10,000 units/mL) has been used, but some reactive patients still will be missed. When commercially available β-lactams such as amoxicillin, penicillin G and ampicillin are used alone for skin testing, as many as 15% of patients with β-lactam allergies will be missed.[43] Skin testing with the major and minor determinants has been shown to facilitate the safe use of penicillin in up to 90% of patients with a history of immediate penicillin allergy.[109] Less than 1% of patients with a negative history, and up to 72% of patients with a convincing positive history of penicillin allergy have skin test positive reactivity.[110] In patients who report a history of penicillin allergy but are skin test negative, the risk of resensitization (i.e., conversion to a positive skin test) following a course of penicillin ranges from 1% to 28%.[46] The procedure for performing penicillin skin testing is given in Table 97–5.

A negative penicillin skin test indicates that the risk of life-threatening immediate reactions is extremely low with administration of penicillin or other β-lactams. Such patients are candidates for treatment with full therapeutic doses of a penicillin or a related β-lactam. Certain types of patients (e.g., those with dermatographism, taking antihistamines) may be unsuitable for skin testing because a false-positive or false-negative test may result. To prevent interference with skin testing, antihistamines should be discontinued at least one week prior to skin testing. Penicillin is the only drug for which the predictive value of skin testing has been well established. Although the negative predictive value is high, penicillin skin testing with the major and minor determinants does not identify those patients who are at risk for unique side chain-mediated reactions to β-lactams (e.g., third generation cephalosporins, piperacillin). Dilute concentrations of amoxicillin and piperacillin have been used to skin test

TABLE 97-5 Procedure for Performing Penicillin Skin Testing

A. Percutaneous (Prick) Skin Testing

Materials	Volume
Pre-Pen 6 × 10^6 M (currently not commercially available in the United States)	1 drop
Penicillin G 10,000 units/mL	1 drop
β-Lactam drug 3 mg/mL	1 drop
0.03% albumin-saline control	1 drop
Histamine control (1 mg/mL)	1 drop

1. Place a drop of each test material on the volar surface of the forearm.
2. Prick the skin with a sharp needle inserted through the drop at a 45° angle, gently tenting the skin in an upward motion.
3. Interpret skin responses after 15 minutes.
4. A wheal at least 2 × 2 mm with erythema is considered positive.
5. If the prick test is nonreactive, proceed to the intradermal test.
6. If the histamine control is nonreactive, the test is considered uninterpretable.

B. Intradermal Skin Testing

Materials	Volume
Pre-Pen 6 × 10^6 M (currently not commercially available in the United States)	0.02 mL
Penicillin G 10,000 units/mL	0.02 mL
β-Lactam drug 3 mg/mL	0.02 mL
0.03% albumin-saline control	0.02 mL
Histamine control (0.1 mg/mL)	0.02 mL

1. Inject 0.02–0.03 mL of each test material intradermally (amount sufficient to produce a small bleb).
2. Interpret skin responses after 15 minutes.
3. A wheal at least 6 × 6 mm with erythema and at least 3 mm greater than the negative control is considered positive.
4. If the histamine control is nonreactive, the test is considered uninterpretable.

Antihistamines may blunt the response and cause false-negative reactions.

for side chain mediated reactions.[43–45] The value of skin testing to predict the risk of allergic reactions to other antibiotics (e.g., sulfonamides, tetracyclines, fluoroquinolones) is largely unknown.

Skin testing is used to identify patients at risk for hypersensitivity reactions to carboplatin. The negative predictive value of intradermal skin testing with carboplatin has been shown to be 98% to 99% in patients who have received a number of treatment courses.[92]

DESENSITIZATION

For some patients with history of immediate penicillin or β-lactam allergy, no reasonable alternatives exist, and penicillin or a related β-lactam may be necessary for treatment of severe, life-threatening infection. In this situation, desensitization to the specific β-lactam required for treatment of the infection should be considered. Desensitization can reduce the risk of an IgE-mediated reaction such as anaphylaxis by rendering the mast cells less responsive to degranulation. Desensitization does not influence the likelihood of other types of reactions such as exfoliative dermatitis or SJS.

Desensitization should be performed by a physician experienced in the risks and management of severe allergic reactions in a hospital setting with resuscitation equipment available. The potential risks and benefits should be discussed with the patient. Desensitization should be performed with the specific β-lactam antibiotic that will be administered for treatment of the patient's infection. Prior to initiating the protocol, the patient should be stabilized and fluid, pulmonary, and cardiovascular function optimized. Premedications (antihistamines or corticosteroids) should not be used because these agents may mask the early signs of acute reactions and do not reliably reduce the severity of acute reactions. Approximately one third of patients who have undergone desensitization experience

TABLE 97-6 Protocol for Oral Desensitization

	Phenoxymethyl Penicillin			
Step[a]	*Concentration (units/mL)*	*Volume (mL)*	*Dose (units)*	*Cumulative Dose (units)*

mild, transient allergic reactions either during the desensitization procedure or during penicillin therapy.[34] Patients who can take oral medication should undergo desensitization with oral drug. Once the desensitization protocol is begun, it should not be interrupted except for severe reactions. Antihistamines or epinephrine can be administered to treat reactions. In addition, if the patient completes the desensitization regimen and then undergoes full dose treatment, a lapse between doses of as few as 24 hours can allow for reemergence of sensitivity. Protocols for oral and intravenous penicillin desensitization are listed in Tables 97–6 and 97–7.

TABLE 97-7 Parenteral Desensitization Protocol

Injection No.	Benzylpenicillin Concentration (units)	Volume (mL)	Route
1[a,b]	100	0.1	ID

Protocols for desensitization with other β-lactam antibiotics are also available.[111,112]

Skin tests to penicillin often become negative during and shortly after desensitization. The mechanism by which desensitization is protective is unclear. It does not appear that penicillin-specific IgE is neutralized or that IgG as "blocking antibody" is produced. One possible explanation is that basophils and mast cells attain some degree of tolerance on exposure to the antigen.

Although most reactions to trimethoprim-sulfamethoxazole in HIV-infected patients are not considered to be IgE mediated, the term *trimethoprim–sulfamethoxazole desensitization* is commonly recognized. The underlying mechanism by which desensitization to trimethoprim–sulfamethoxazole is achieved in these patients remains unknown. A number of protocols for trimethoprim–sulfamethoxazole desensitization are available, and many are also referred to as graded challenge protocols. Since these regimens have not been compared in controlled clinical trials, there is no preferred regimen. Desensitization of trimethoprim–sulfamethoxazole can be achieved within 2 days in most AIDS patients.[1,113] This can be accomplished by using the following schedule of oral doses (milligrams of sulfamethoxazole–trimethoprim): day 1: 9 AM, 4 and 0.8 mg; 11 AM, 8 and 1.6 mg; 1 PM, 20 and 4 mg; 5 PM, 40 and 8 mg; day 2: 9 AM, 80 and 16 mg; 3 PM, 160 and 32 mg; 9 PM, 200 and 40 mg; day 3: 9 AM, 400 and 80 mg, and 400 and 80 mg daily thereafter. With this desensitization regimen, the failure rate was associated with higher relative and absolute CD4 cell counts. Other investigators have described a 6-hour oral graded challenge in HIV-infected patients.[114] and a more gradual 9-day oral regimen.[115] Desensitization should not be attempted in any patient with history of an exfoliative reaction to trimethoprm-sulfamethoxazole.

Both rapid (over less than 4 hours) and traditional desensitization protocols are available for aspirin and clopidogrel.[116,117] Aspirin desensitization is more effective in patients with history of aspirin-induced asthma as compared to the angioedema/urticarial presentation.[65] A rapid 12-step protocol has been shown to be safe and effective for desensitizing patients to a variety of chemotherapeutic agents including carboplatin, cisplatin, oxaliplatin, paclitaxel, and rituximab.[93]

GRADED CHALLENGE

Also known as test dosing, a graded drug challenge involves the gradual introduction of a drug when there is a risk of reactivity. A graded drug challenge does not modify the immune response or allow for more rapid desensitization.[111] Instead, graded challenge is used when the risk of a severe reaction to a drug on re-exposure is low, no alternative drug is equally effective, and a reliable skin testing method is not available. A classic example is the gradual re-introduction of trimethoprim–sulfamethoxazole in a patient who had a mild maculopapular rash to the drug in the past. Graded challenge may also be used to test for cross-reactivity when the risk of a severe reaction is low (e.g., a patient with history of allergy to one cephalosporin who now requires a cephalosporin having a dissimilar R1 side chain).[111] Graded challenge protocols have been described for the slow introduction of furosemide in a patient with heart failure and history of sulfonamide allergy.[118] Challenge dosing is not recommended when there is history of a severe drug allergy (e.g., anaphylaxis, SJS, TEN). Premedications should not be used because they may mask signs of an early breakthrough allergic reaction. The starting dose is typically 1/10th to 1/100th of the therapeutic dose and the oral route of drug administration is preferred to limit the risk of a severe reaction.[111] If no reaction occurs to the initial dose, the dose may be increased in 2- to 5-fold increments and administered every 30 to 60 minutes until the full therapeutic dose is achieved.[45,111] There is no standard protocol for graded challenge dosing; a therapeutic dose may be achieved over a matter of hours or days. Due to the risk of break-through allergic reactions, graded challenges should be performed in monitored settings.

ABBREVIATIONS

APC: antigen-presenting cell

DRESS: drug rash with eosinophilia and systemic symptoms

HLA: human leukocytic antigen

IgE: immunoglobulin E

LT: leukotriene

NSAID: nonsteroidal antiinflammatory drug

PAF: platelet-activating factor

PG: prostaglandin

PPD: purified protein derivative

SJS: Stevens Johnson syndrome

SLE: systemic lupus erythematosus

TEN: toxic epidermal necrolysis

CHAPTER 98

Solid-Organ Transplantation

HEATHER J. JOHNSON AND KRISTINE S. SCHONDER

KEY CONCEPTS

1. A combination of two to four immunosuppressive drugs is used to target different levels of the immune cascade to prevent allograft rejection and allow lower doses of the individual agents to minimize their toxicity.
2. Calcineurin inhibitors (CIs), such as cyclosporine and tacrolimus, which inhibit interleukin (IL)-2 and thus block T-cell activation are the backbone of immunosuppressive regimens. However, they are associated with significant adverse effects, namely, nephrotoxicity and neurotoxicity.
3. Calcineurin inhibitor–induced nephrotoxicity is one of the most common side effects observed in transplant recipients and is the leading cause of renal dysfunction in nonrenal transplant patients. Therapeutic drug monitoring is used in an attempt to optimize the use of calcineurin inhibitors.
4. Corticosteroids are a key component of immunosuppressive regimens because they block the initial steps in allograft rejection. However, the adverse effects associated with their long-term use have prompted the investigation of corticosteroid-free immunosuppressive protocols. Corticosteroids remain the cornerstone of the treatment of allograft rejection.
5. Antiproliferative agents such as azathioprine and mycophenolate inhibit T-cell proliferation by altering purine synthesis to prevent acute rejection. Bone marrow suppression is the most significant adverse effect associated with these agents.
6. Sirolimus and everolimus exert their activity by inhibiting the mTOR (mammalian target of rapamycin) receptor, which alters T-cell response to IL-2. The adverse effects associated with sirolimus include thrombocytopenia, anemia, and hyperlipidemia.
7. Antibody preparations that target specific receptors on T cells are classified as depleting or nondepleting. Most lymphocyte-depleting antibodies are associated with significant infusion-related reactions.
8. Long-term allograft and patient survival is limited by chronic rejection, cardiovascular disease, and long-term immunosuppressive complications such as malignancy.

Solid-organ transplantation provides a lifesaving treatment for patients with end-stage cardiac, kidney, liver, lung, and intestinal disease. About 250 U.S. hospitals offer transplant services, and pharmacists are often an integral part of the transplant team. The Centers for Medicare and Medicaid Services regulations require that transplant programs have a multidisciplinary team including individuals with experience in pharmacology. While the regulations do not specifically state that each center must have a pharmacist, a pharmacist would certainly provide the desired expertise in transplant pharmacotherapy that the regulations mandate.[1]

With the success of transplantation, an increasing number of transplant recipients are in our communities. By the end of 2005 there were more than 160,000 people living with a solid-organ transplant in the United States.[1] In 2008, 27,963 solid-organ transplants were performed. Kidney transplants remain the most common; 10,551 were from cadaveric donors and 5,967 from living donors. The next most frequently transplanted organ was the liver, with 6,070 from cadaveric donors and 249 from living donors. Heart and pancreas (or combined kidney–pancreas) transplants account for over 2,100 and almost 1,300 transplants, respectively; over 1,900 lung transplants were performed as well.[1] While the demand for transplantation continues to grow, the number of cadaveric donors has remained relatively stable during the past decade. In 2008, more than 100,000 persons in the United States were waiting for a transplant (almost 70,000 people were awaiting a kidney, 16,000 a liver, and almost 3,000 were on the list for a heart transplant). Median waiting time for a cadaveric kidney is more than 3.5 years. For liver transplantation the median time to transplant is about 1 year, whereas for heart transplantation it is approximately 6 months. For heart, liver, and lung transplantation clinical status is an important factor affecting waiting times, with the sickest patients receiving priority for available organs.[1]

To increase the number of organs available for transplantation, several strategies have been employed in the past several years. The use of living donors for renal transplantation represents over one third of all kidney transplants, more than any other organ. Living-donor transplantation is also becoming increasingly important for those with end-stage liver and lung disease. Efforts to expand the cadaveric donor pool have included relaxation of age restrictions, development of better preservation solutions, use of "extended-criteria" and non–heart-beating donors, and the transplantation of one liver to more than one recipient, as well as the implantation of only a segment of a liver. Although very controversial, others advocate the creation of a regulated system for compensating individuals in a monetary fashion for the "donation" of a kidney.

Despite all these efforts, patients continue to die awaiting transplantation. In 2004, more than 7,000 people who were on transplantation waiting lists died. In all areas, efforts have been made to improve organ allocation by moving toward allocation based primarily on "medical necessity" versus time on the waiting list.

TABLE 98-1 Organ-Specific Patient and Graft Survival Rates[4]

Organ	Patient Survival (%)		Graft Survival (%)	
	1 Year	*5 Years*	*1 Year*	*5 Years*
Kidney				
Living donor	98.0	90.3	97.3	67.5
Deceased donor	94.8	80.6	90.0	80.2
Liver				
Living donor	90.6	76.1	84.1	68.6
Deceased donor	86.9	73.6	82.3	67.6
Heart	87.8	74.4	87.3	73.2

Although dialysis can be used for an extended period of time to partially replace the function of the kidneys, such options are not readily available for most liver and heart transplantation candidates. Left ventricular assist devices are now used commonly as a bridge to transplantation for many heart transplantation candidates, however, hepatocyte transplantation and artificial liver support remain investigational alternatives or bridges to liver transplantation.[2]

Patient and graft survival rates following transplantation have improved significantly over the past 30 years as a result of advances in pharmacotherapy, surgical techniques, organ preservation, and the postoperative management of patients (Table 98–1). In this chapter the epidemiology of end-stage kidney, liver, and heart disease is briefly reviewed, the pathophysiology of organ rejection is reviewed, the pharmacotherapeutic options for individualized immunosuppressive regimens are critiqued, and the unique complications of these regimens along with the therapeutic challenges they present are discussed.

EPIDEMIOLOGY AND ETIOLOGY

KIDNEY

Renal transplantation is the preferred long-term therapeutic option for most patients with end-stage renal disease because it provides patients with the greatest potential improvement in quality of life. Dialysis catheter-related infections, peritoneal dialysis-associated peritonitis, and scheduled dialysis treatments are avoided, and dietary restrictions are fewer. Patients who receive a renal transplant before the initiation of dialysis have markedly improved quality of life and prolonged life expectancy.[3] The use of living-donor transplantation has made this increasingly possible. Although the analysis of quality of life is complex, patients generally report improved quality of life following transplantation as compared with patients on maintenance dialysis.[4]

Diabetes mellitus, hypertension, and glomerulonephritis are the most common causes of end-stage renal disease leading to kidney transplantation and account for more than 70% of patients (see Chap. 52 and 53).[5] Patients with medical conditions such as unstable cardiac disease or recently diagnosed malignancy, for whom the risk of surgery or chronic immunosuppression would be greater than the risks associated with chronic dialysis, are generally excluded from consideration for transplantation.

CLINICAL CONTROVERSY

The life expectancy of patients infected with human immunodeficiency virus (HIV) has greatly improved in the recent decade, and more patients suffer end-stage organ failure due to co-infection with hepatitis or from HIV-nephropathy. Many clinicians do not consider patients infected with HIV to be appropriate candidates for transplantation because of the relative scarcity of available organs. Some centers consider transplantation of only live donor organs or extended-criteria organs.

LIVER

Noncholestatic cirrhosis (hepatitis C, alcoholic cirrhosis, hepatitis B, nonalcoholic steatohepatitis, and autoimmune hepatitis) is the primary cause of end-stage liver disease and more than 70% of liver transplant recipients have been diagnosed with one of these conditions.[1] Livers are allocated based on a United Network for Organ Sharing-adapted, Model for End-stage Liver Disease (MELD) score. This score, based on serum creatinine concentration, total serum bilirubin concentration, international normalized ratio, and etiology of cirrhosis, has been demonstrated to be a useful tool to predict impending mortality.

There are few absolute contraindications to liver transplantation. Patients should be free from active alcohol or substance abuse. Although hepatitis B and C can recur in the transplanted liver, these are not absolute contraindications to liver transplantation.[2,6]

HEART

Cardiac transplant candidates are typically patients with end-stage heart failure who have New York Heart Association class III or IV symptoms despite maximal medical management and have an expected 1-year mortality risk of 25% or greater without a transplant.[7,8] Idiopathic cardiomyopathy and ischemic heart disease account for heart failure in more than 90% of heart transplantation recipients.[1] Other etiologies include valvular disease, retransplantation for graft atherosclerosis or dysfunction, and congenital heart disease. Chapters 20 and 21 discuss the role of heart transplantation as a therapeutic option for patients with heart failure.

Absolute contraindications to orthotopic cardiac transplantation include the presence of an active infection (except in the case of an infected ventricular assist device, which is an indication for urgent transplantation) or the presence of other diseases (e.g. malignancy) that may limit survival and/or rehabilitation and severe, irreversible pulmonary hypertension.

PHYSIOLOGIC CONSEQUENCES OF TRANSPLANTATION

Transplantation is truly lifesaving for heart, liver, and lung transplantation recipients, whereas renal transplantation is associated with improved quality of life and survival when compared with dialysis.[9] Most heart transplantation patients return to New York Heart Association functional class I following transplantation. Although not all return to work, 89.9% of patients consider themselves to have no activity limitations at 1-year follow-up.[10] The specific physiologic consequences of kidney, liver, and heart transplantation are discussed next.

KIDNEY TRANSPLANTATION

The glomerular filtration rate of a successfully transplanted kidney may be near normal almost immediately after transplantation. In some patients, however, the concentration of standard biochemical indicators of renal function, such as serum creatinine and blood urea nitrogen, may remain elevated for several days. Standard formulas used to predict drug dosing rely on a stable serum creatinine and may be inaccurate immediately following transplantation (see Chap. 50).

Although the allograft is able to remove uremic toxins from the body, it may take several weeks for other physiologic complications of chronic renal failure, such as anemia, calcium and phosphate imbalance, and altered lipid profiles, to resolve. The renal production of erythropoietin and 1-hydroxylation of vitamin D may return toward normal early in the postoperative period. Because the onset of physiologic effects may be delayed, continuation of pretransplantation calcitriol, calcium supplementation, and/or phosphate binders may be warranted. The duration of therapy will depend on how rapidly kidney function improves. Patients should be monitored for hypophosphatemia and hypercalcemia.

Primary nonfunction of a renal allograft or delayed graft function (DGF) is characterized by the need for dialysis in the first postop week or the failure of the serum creatinine to fall by 30% of the pretransplantation value. The incidence of DGF in cadaveric renal transplantation ranges from 8% to 50% and results in a slower return of the kidney's excretory, metabolic, and synthetic functions. DGF is associated with prolonged hospital stays, higher costs, difficult management of immunosuppressive therapy, slower patient rehabilitation, and poor graft survival. Other early causes of renal dysfunction such as urethral obstruction or arterial or venous stenosis or thrombosis should be distinguished from DGF.

The primary cause of DGF is acute tubular necrosis (ATN). The incidence of ATN increases when kidneys are harvested from donors who recently experienced a cardiac arrest, from donors who were hypotensive or on vasopressors, or from older donors (age >55 years) and with prolonged periods of ischemia. While cyclosporine and tacrolimus have been implicated in the prolongation of ATN, a clear cause-and-effect relationship has not been established. Nonetheless, most clinicians will decrease calcineurin inhibitor doses in patients with ATN. DGF predisposes patients to acute rejection, possibly as a consequence of decreased calcineurin inhibitor levels and a resultant reduction in the level of immunosuppression.

LIVER TRANSPLANTATION

The physiologic consequences of liver transplantation are complex, involving changes in both metabolic and synthetic function. Postoperatively, the liver transplant recipient will likely have many fluid, electrolyte, and nutritional abnormalities. Biliary tract dysfunction may alter the absorption of fats and fat-soluble drugs.[11] Poor absorption of the lipid-soluble drug cyclosporine improves after successful liver transplantation and reestablishment of bile flow. Vitamin E deficiency and its neurologic complications in liver failure patients are reversed after successful liver transplantation. In stable adult liver transplant patients, the concentrations of retinol and tocopherol are similar to those seen in normal healthy subjects, indicating recovery of transplanted liver production and excretion of bile salts needed for fat-soluble vitamin absorption. Table 98–2 summarizes the effects of liver transplantation on metabolism and renal elimination that are seen in the immediate postoperative period. Most of these changes resolve as liver function normalizes.

The newly transplanted liver fails to function in 10% to 15% of recipients as the result of several different mechanisms. Early graft failure can result from preexisting disease in the donor, and even coagulation defects have been acquired through donor organs. The technical complexity of the operation can produce flaws in revascularization that also lead to graft nonfunction. Surgical complications include portal vein or hepatic artery thrombosis and bile duct leaks. Ischemic injury can also result in early graft dysfunction. While hyperacute rejection in liver transplantation rarely occurs, graft failure in the first 2 postoperative weeks may indicate antibody-mediated graft destruction.

TABLE 98-2 Perioperative Changes in Drug Disposition and Elimination Following Liver Transplantation

	Result	Comment
Serum proteins		
↓ Albumin	↑ Free fraction of drugs usually bound to albumin	Diazepam, salicylic acid binding greater in liver transplant than chronic liver disease because of endogenous binding inhibitors (up to 45 days post-transplant)
↑ Alpha-1-Acid glycoprotein	Lower free fraction of drugs	Lidocaine
Metabolism/elimination		
Microsomal enzymes	↑ CYP2E1 activity	Increased drug metabolism (induction)
	↔ CYP2D6	Unaffected
	↓ CYP activity	Decreased drug elimination (inhibition)
Oxidation	Stable	
Conjugation	Normalizes after transplant	
Biliary function	↓ Absorption of lipophilic compounds ↑ Cyclosporine metabolites in blood	
Renal elimination	Elimination of gentamicin, vancomycin, cephalosporins less than predicted by serum creatinine	Renal elimination of metabolites limited

Adapted from reference 11.

HEART TRANSPLANTATION

The orthotopically transplanted heart is denervated and no longer responds to physiologic stimuli and pharmacologic agents in a normal manner (Table 98–3).[9] Patients, for example, do not experience angina. In situations requiring an increased heart rate such as exercise or hypotension, the denervated heart is unable to acutely increase heart rate but instead relies on increasing the stroke volume. Later in the course of exercise or hypotension, heart rate increases in response to circulating catecholamines. While the maximum exercise capacity of heart transplant recipients is below normal, most patients are able to resume normal lifestyles and reasonably vigorous activity levels. Partial reinnervation may occur over time, thereby facilitating more normal physiologic and pharmacologic responses and better exercise capacity.[10]

A number of autoregulatory, anatomic, and physiologic responses present in the normal heart are interrupted or blunted for the first 6 weeks after transplantation. The donor sinus node function may be impaired by preservation injury, direct surgical trauma at excision, the presence of long-acting antiarrhythmics (e.g., amiodarone) taken prior to transplant by the recipient, and a lack of "conditioning" responsiveness to catecholamines.[10] Consequently, the transplanted heart generally requires chronotropic support with either milrinone or pacing in the perioperative period to maintain a heart rate of 90 to 110 beats per minute and satisfactory hemodynamics (i.e., blood pressure, urine output, and tissue perfusion). Approximately 10% to 20% of transplant patients will have persistent chronotropic incompetence requiring either short courses of medications, such as terbutaline or theophylline, or permanent cardiac pacing.

Right ventricular function is frequently impaired, presumably as a result of preservation injury and elevated pulmonary vascular

TABLE 98-3 Altered Responses to Cardiac Drugs in the Denervated Transplanted Heart

Drug	Effect	Mechanism	Comment
Digitalis	Normal inotropic effect; minimal effect on AV node	Direct myocardial effect; denervation	
Atropine	No effect on AV node	Denervation	
Adrenaline/noradrenaline	Increased contractility; increased chronotropy	Denervation; hypersensitivity	Increased cardiac output mediated by increased heart rate
Isoproterenol	Normal increase in contractility; normal increase in chronotropy	No neuronal uptake	
Quinidine	No vagolytic effect	Denervation	
Verapamil	AV block	Direct effect	
Nifedipine	No reflex tachycardia	Denervation	
Hydralazine	No reflex tachycardia	Denervation	
β-Blocker	Increased antagonist effect	Denervation	Impaired heart rate response, use sparingly
Adenosine	Negative chronotropic effect	Hypersensitivity; effect on sinus node of denervated heart	Life-threatening asystole (>0.5 min) may occur if used to treat supraventricular arrhythmia or stress testing
Acetylcholine	Negative chronotropic effect	Hypersensitivity; effect on sinus node of denervated heart	

AV, atrioventricular.

Reproduced from Deng MC. Heart failure: Cardiac transplantation. Heart 2002;87:177–184 with permission from the BMJ Publishing Group Ltd.

resistance. A "restrictive" hemodynamic pattern may be present initially but usually improves in 6 weeks following transplantation. Donor–recipient size mismatch may contribute to early post-transplantation hemodynamic abnormalities characterized by higher right and left ventricular end-diastolic pressures. Supraventricular arrhythmias are usually transient and may result from overvigorous use of catecholamines or milrinone. If this type of arrhythmia occurs after the perioperative period, the astute clinician should consider the possibility of acute rejection.

Myocardial depression frequently occurs and generally requires inotropic support with agents such as dobutamine, milrinone, and epinephrine. On occasion, intra- or postoperative administration of vasodilators, including nitric oxide, and inotropic agents may be necessary to treat right-sided failure in the transplant patient; milrinone and isoproterenol are preferred in this setting.

Persistent abnormalities of diastolic function are often noted in the transplanted heart such that intracardiac pressures increase in an exaggerated fashion in response to exercise and/or volume infusion.[10] These abnormalities are due in part to denervation, but also to acute rejection or to the scarring secondary to previously treated rejection episodes, hypertension, or cardiac allograft vasculopathy.

Hypertension may occur following surgery secondary to the effect of elevated catecholamine levels and systemic vascular resistance as the residual effects of end-stage heart failure on the healthy heart. Systolic blood pressure should be maintained at 110 to 120 mm Hg to enhance cardiac function. In the acute post-transplantation period, intravenous nitroprusside or nitroglycerin may be needed, whereas oral angiotensin-converting enzyme inhibitors (ACEIs) and/or amlodipine are commonly used once the patient can ingest oral medications.

PATHOPHYSIOLOGY OF REJECTION

GENERAL CONCEPTS

Rejection of any transplanted organ is primarily mediated by activation of alloreactive T cells and antigen-presenting cells such as B lymphocytes, macrophages, and dendritic cells. Acute allograft rejection is caused primarily by the infiltration of T cells into the allograft, which triggers inflammatory and cytotoxic effects on the graft. Complex interactions between the allograft and cellular cytokines, cell-to-cell interactions, CD4+ and CD8+ T cells, and B cells ultimately lead to chronic rejection and graft loss if adequate immunosuppression is not maintained.[12]

The sequence of events that underlies graft rejection is recognition, via MHC class I and II antigens, of the donor's histocompatibility differences by the recipient's immune system, recruitment of activated lymphocytes, initiation of immune effector mechanisms, and finally graft destruction. The specifics of this immune cascade of organ rejection are discussed in Chapter 95. The complex nature of cytokine interactions makes it very difficult to design drugs with exclusive actions (Fig. 98–1).

Rejection of the transplanted tissue can take place at any time following surgery and is classified clinically as hyperacute rejection, acute cellular rejection, and/or humoral or chronic rejection.[13]

Efforts are made to allocate well-matched, according to human leukocyte antigens (HLA)-A, -B, and -DR, kidneys to minimize rejection and enhance survival rates. However, the benefit of having no recipient donor mismatches may be negated by excessive cold ischemia time (>36 hours) and donor age older than 60 years. HLA tissue matching is not performed routinely before transplantation for livers and hearts because organ availability is more limited and the optimal cold ischemia time is shorter. However, if the potential recipient's blood is reactive against a panel of random donor blood samples (i.e., panel reactive antibody [PRA] >10% to 20%), a negative T-cell crossmatch is required prior to transplantation. Transplanted organs must be matched for ABO blood group compatibility with the recipient as ABO mismatching will result. Liver transplantation may be carried out in emergency situations across ABO blood groups, but survival is lower.

HYPERACUTE REJECTION

Hyperacute rejection may be evident within minutes of the transplantation procedure when preformed donor-specific antibodies are present in the recipient at the time of the transplant. Hyperacute rejection can also be induced by immunoglobulin G antibodies that bind to antigens on the vascular endothelium, such as class I MHC, ABO, and vascular endothelial cell antigens. Tissue damage can be mediated through antibody-dependent, cell-mediated cytotoxicity or through activation of the complement cascade. The ischemic damage to the microvasculature rapidly results in tissue necrosis.

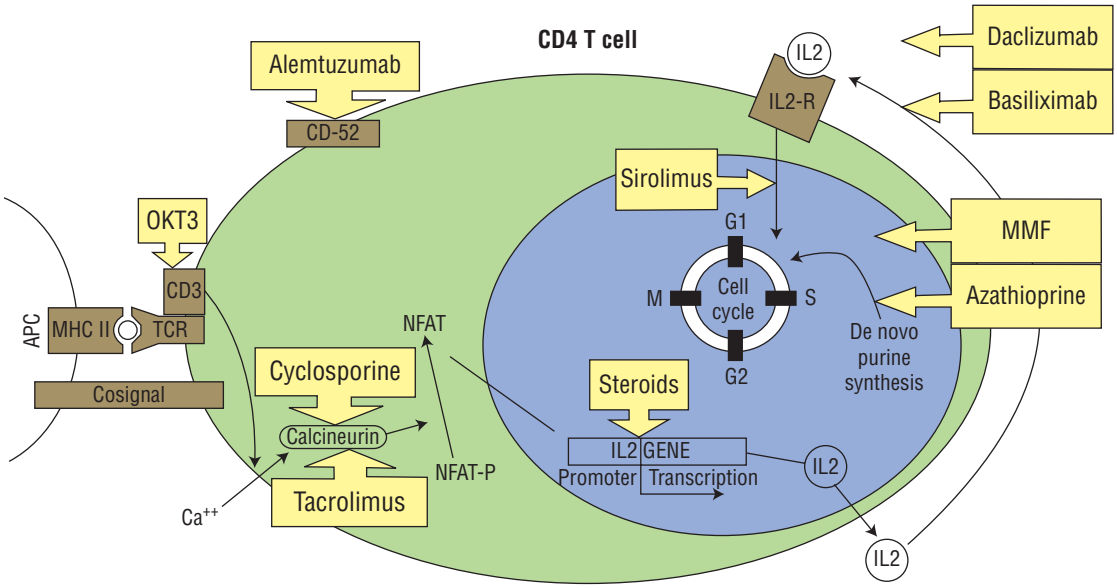

FIGURE 98-1. Stages of CD4 T-cell activation and cytokine production with identification of the sites of action of different immunosuppressive agents. Antigen major histocompatibility complex (MHC) II molecule complexes are responsible for initiating the activation of CD4 T cells. These MHC-peptide complexes are recognized by the T-cell recognition complex (TCR). A costimulatory signal initiates signal transduction with activation of second messengers, one of which is calcineurin. Calcineurin removes phosphates from the nuclear factors (NFAT-P) allowing them to enter the nucleus. These nuclear factors specifically bind to an interleukin (IL)-2 promoter gene facilitating IL-2 gene transcription. Interaction of IL-2 with the IL-2 receptor (IL-2R) on the cell membrane surface induces cell proliferation and production of cytokines specific to the T cell. (APC, antigen-presenting cells; MMF, mycophenolate mofetil.) (*Reprinted from Ann Thorac Surg, Vol. 77, Mueller XM, Drug immunosuppressive therapy for adult heart transplantation. Part I. Immune response to allograft and mechanism of action of immunosuppressants, pages 354–362, Copyright © 2004, with permission from Elsevier.*)

Hyperacute rejection has become uncommon in kidney and heart transplants. A positive crossmatch presents a serious risk for graft failure even if hyperacute rejection does not occur. A negative lymphocytotoxicity crossmatch does not entirely rule out the possibility of hyperacute rejection because non-MHC antigens on the vascular endothelium can serve as targets of donor-specific antibodies. Early graft dysfunction is treated with supportive care and retransplantation if possible. The reason for the rarity of hyperacute rejection in liver transplantation is not fully understood, but the local release of cytokines may alter the immunologic reaction in the liver.

ACUTE CELLULAR REJECTION

Acute rejection is most common in the first few months following transplantation but can occur at any time during the life of the allograft. Acute cellular rejection is mediated by alloreactive T-lymphocytes that appear in the circulation and infiltrate the allograft through the vascular endothelium. After the graft is infiltrated by lymphocytes, the cytotoxic cells specifically target and kill the functioning cells in the allograft. At the same time, local release of lymphokines attracts and stimulates macrophages to produce tissue damage through a delayed hypersensitivity–like mechanism. These immunologic and inflammatory events lead to nonspecific signs and symptoms including pain and tenderness over the graft site, fever, and lethargy.

Kidney

Acute rejection, which may affect up to 20% of patients during the first 6 months following transplantation, is evidenced by an abrupt rise in serum creatinine concentration of ≥30% over baseline. A specific histologic diagnosis can be obtained via biopsy of the allograft and is often used to guide therapy for rejection. A biopsy specimen with a diffuse lymphocytic infiltrate is consistent with acute cellular rejection. After the diagnosis of rejection has been confirmed, the potential risks and benefits of specific antirejection therapies must be evaluated. Hypertension often worsens during an episode of rejection, and edema and weight gain are common as a result of sodium and fluid retention. Symptomatic azotemia may also develop in severe cases.

Liver

The liver is more likely to promote immunologic tolerance than the other vascularized organs. Approximately 18% of liver transplantation recipients will experience a rejection episode in the first post-transplant year. The clinical signs of acute cellular rejection include leukocytosis and a change in the color or quantity of bile for those who still have an external drainage tube in place. A serum bilirubin 50% over baseline or increases in hepatic transaminases to values more than three times the upper limit of normal, are sensitive markers of rejection. Although a liver biopsy provides definitive evidence of the diagnosis of rejection, a prompt response to antirejection medication has also proven useful as a means to differentiate rejection from other causes of hepatic dysfunction.

Heart

More than 60% of heart transplantation recipients will experience at least one episode of acute rejection during the first year, with 90% of all rejections occurring within the first 6 months.[14] Because rejection of the cardiac allograft is not necessarily accompanied by overt clinical signs or symptoms and because the incidence of acute rejection is highest during this time period, endomyocardial biopsies are often performed at regularly scheduled intervals following transplantation.[15] A typical biopsy schedule would be weekly for the first postoperative month, biweekly for the next 2 months, and monthly to bimonthly through the remainder of the first post-transplant year. Nonspecific symptoms, including low-grade fever, malaise, mild reduction in exercise capacity, heart failure, or atrial arrhythmias may also be evident and if present are reflective of a more severe rejection episode.

ANTIBODY-MEDIATED REJECTION

Antibody-mediated rejection (AMR), sometimes referred to as vascular or humoral rejection, is characterized by the presence of antibodies directed against HLA antigens present on the donor vascular endothelium. It can be characterized by capillary deposition of immunoglobulins, complement, and fibrinogen on immunofluorescence staining. Circulating immune complexes often precede humoral rejection. This form of rejection is less common than cellular rejection and generally occurs in the first 3 months after transplantation. It is associated with an increased fatality rate and appears to be more common when antilymphocyte antibodies are used for rejection prophylaxis. An increased risk of humoral rejection is associated with female gender, elevated PRA, cytomegalovirus seropositivity, a positive crossmatch, and prior sensitization to OKT3 (muromonab CD3).[16] Strategies to reverse humoral rejection include plasmapheresis, often in combination with intravenous immunoglobulin, high-dose intravenous corticosteroids, antithymocyte globulin, cyclophosphamide, rituximab, and mycophenolate mofetil.

CHRONIC REJECTION

Chronic rejection is a major cause of graft loss. It presents as a slow and indolent form of acute cellular rejection, in which the involvement of the humoral immune system and antibodies against the vascular endothelium appear to play a role. Persistent perivascular and interstitial inflammation is a common finding in kidney, liver, and heart transplantation. As a result of the complex interaction of multiple drugs and diseases over time, it is difficult to delineate the true nature of chronic rejection. Unlike acute rejection, chronic rejection is not reversible with any immunosuppressive agents currently available.

Kidney

Advances in the management of acute rejection during the last decade have increased the duration of functioning grafts from living and cadaveric donors by more than 70%.[17] Chronic allograft nephropathy remains the most common cause of graft loss in the late post-transplantation period (>1 year). The histopathologic characteristics of chronic allograft nephropathy include vascular intimal hyperplasia, tubular atrophy, interstitial fibrosis, and chronic glomerulopathy. Structural changes are seen in as many as 40% of kidney transplantation patients 1 year after transplantation and may present as early as 3 months.[18] Hypertension, proteinuria, and a progressive decline in renal function represent the classic clinical triad of chronic allograft nephropathy. Factors that contribute to the development of chronic allograft nephropathy include calcineurin inhibitor nephrotoxicity, polyomavirus infection, hypertension, donor-related factors including ischemia time and undetected kidney disease in the donor kidney, and recurrence of the primary kidney disease in the recipient.

Liver

Approximately 3 to 5% of transplant livers are affected by chronic rejection, which is characterized by an obliterative arteriopathy and the gradual loss of bile ducts, often referred to as the vanishing bile duct syndrome. Initially patients experience an asymptomatic rise in the alkaline phosphatase and γ-glutamyl transpeptidase. As levels of bilirubin increase, patients become jaundiced and may experience itching.

Heart

Cardiac allograft vasculopathy, characterized by accelerated intimal thickening or development of atherosclerotic plaques, is the leading cause of graft failure and death in heart transplant recipients.[19] Endothelial injury, caused by both cell-mediated and humoral responses, is the first step in the process. Vasculopathy is restricted to the transplanted allograft. Routine surveillance with coronary angiography, intravascular ultrasound, or other procedures can aid in the diagnosis of vasculopathy. Evidence of cardiac allograft vasculopathy can be seen in as many as 14% of patients within 1 year of transplantation and in as many as 50% of patients within 5 years.[19] While chronic rejection of the kidney or liver allograft is generally not amenable to treatment, 3-hydroxy-3-methylglutaryl-coenzyme A (HMGCoA) reductase inhibitors and ACEIs have been used to decrease the incidence of vasculopathy in the heart allograft.[19] More recently, sirolimus and everolimus have been shown to reduce the incidence and slow progression of cardiac allograft vasculopathy.[19] Percutaneous transluminal coronary angioplasty and coronary artery bypass grafting have been used in severe cases of vasculopathy; these procedures, however, are limited by significantly increased mortality compared with the general population.[19]

TREATMENT

Immunosuppression

DESIRED OUTCOME

Immediately following surgery, the primary goal of therapy is to prevent hyperacute and acute rejection. The high doses of immunosuppressants required to achieve this goal, if maintained long term, may result in serious complications such as nephrotoxicity, infection, thrombocytopenia, and drug-induced diabetes. Therefore rapid dosage reductions are frequently used to minimize these effects. Transplant immunosuppression must be balanced to optimize both graft and patient survival.

GENERAL APPROACH TO TREATMENT

1 A multidrug approach is rational from an immunomechanistic viewpoint because the many agents have overlapping and potentially synergistic mechanisms of action. Furthermore, the use of a multidrug immunosuppression regimen may allow the use of lower doses of individual agents, thus reducing the severity of dose-related adverse effects (Fig. 98–2). The protocols and individual drug regimens tend to be medical center specific. Although induction therapy may not be uniformly used, in almost every setting, patients receive IV methylprednisolone intraoperatively. Patients may also receive a descending dose of methylprednisolone over the first 5 to 7 postoperative days before beginning oral prednisone. Protocols generally combine a drug from two or three of the following classes: calcineurin inhibitors, antimetabolites or proliferation signal inhibitors, and corticosteroids.

If rejection is suspected, a biopsy can be done for definitive diagnosis or the patient may be empirically treated for rejection. Empiric treatment generally involves administration of high-dose corticosteroids, usually 500 to 1,000 mg of methylprednisolone intravenously for one to three doses. If signs and symptoms of rejection are resolved with empiric therapy, the maintenance immunosuppressive regimen is generally modified to provide a greater level of overall immunosuppression. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection with polyclonal and monoclonal antibodies being reserved for moderate to severe rejections or those that have not responded to a course of corticosteroids.

Induction Therapy

Induction therapy involves the use of a high level of immunosuppression, at the time of transplantation, with or without the immediate

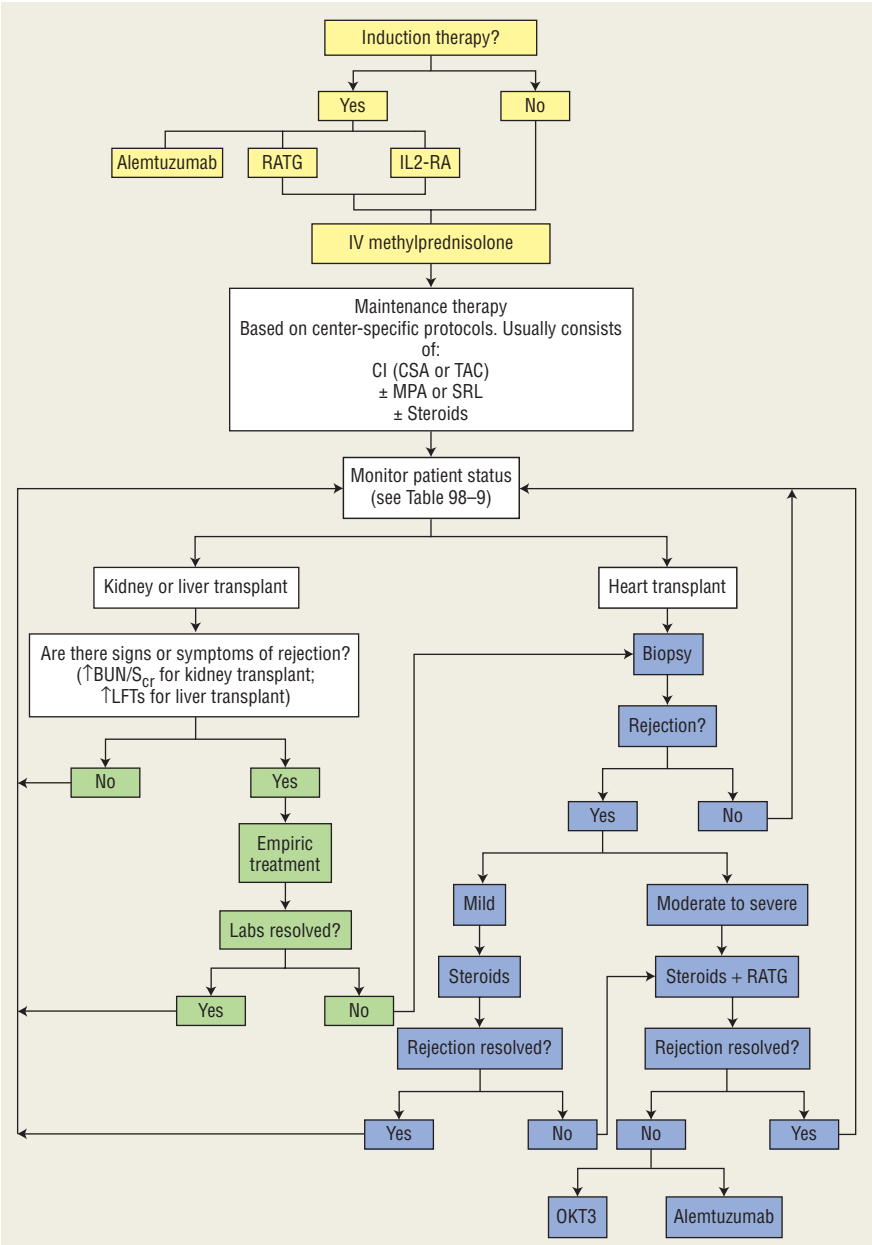

FIGURE 98-2. General approach to solid-organ transplant immunosuppression. (BUN, blood urea nitrogen; CI, calcineurin inhibitor; CSA, cyclosporine; IL2RA, interleukin-2 receptor antagonist; LFTs, liver function tests; MPA, mycophenolic acid; OKT3, muromonab CD3; RATG, rabbit antithymocyte immunoglobulin; S_{cr}, serum creatinine; SRL, sirolimus; TAC, tacrolimus.)

introduction of cyclosporine or tacrolimus (see Fig. 98–2). Induction therapy consists of one of two perioperative immunosuppressive strategies: (a) the provision of a highly intense level of immunosuppression, often on the basis of patient-specific risk factors such as age and race, or (b) the use of antibody therapy to provide enough immunosuppression to delay the initiation of therapy with the nephrotoxic calcineurin inhibitors. The rationale for delayed calcineurin inhibitor administration varies slightly depending on the type of transplant. In renal transplantation, the newly transplanted kidney is very susceptible to nephrotoxic injury, whereas in liver and heart transplantation, the idea is to protect patients with preexisting renal insufficiency from further insults during the perioperative period. Additionally, calcineurin inhibitor dosage adjustment to maintain target concentrations may be difficult in the perioperative period secondary to fluctuation of gastrointestinal motility and enteral intake.

Acute Rejection

The primary goal of acute rejection therapy is to minimize the intensity of the immune response and prevent irreversible injury to the allograft. The available options include (a) increasing the doses of current immunosuppressive drugs, (b) "pulse" corticosteroids with subsequent dose taper, (c) addition of another immunosuppressant indefinitely, or (d) short-term treatment with a polyclonal or monoclonal antibody. The treatment of acute rejection almost always begins with "pulse" corticosteroid therapy for several days (oral or intravenously). Recent data in renal transplantation indicate, however, that African Americans do not respond as well to corticosteroids; thus antithymocyte globulin may be preferable for this patient population.[20]

Cytolytic agents are often reserved for those with corticosteroid-resistant rejection, signs of hemodynamic compromise (heart), or more severe rejections. Other innovative forms of therapy for persistent or intractable rejection have been investigated, including mycophenolate mofetil, tacrolimus, low-dose methotrexate, sirolimus, total lymphoid irradiation, and plasmapheresis and intravenous immunoglobulin. Prophylactic agents such as valganciclovir, nystatin, trimethoprim-sulfamethoxazole, H_2-receptor antagonists or proton-pump inhibitors, and/or antacids may be added to minimize adverse effects associated with these intensive immunosuppression regimens.

Maintenance Therapy

The goal of maintenance immunosuppression is to prevent acute and chronic rejection while minimizing drug-related toxicity. As patients progress through the post-transplant course, the risk of acute rejection decreases, thus allowing the clinician to gradually reduce the doses of immunosuppressants or in some cases totally withdraw them over a period of 6 to 12 months. Transplant organ and type (cadaveric versus living-donor), the degree of HLA mismatch, time after transplantation, post-transplantation complications (including the number of acute rejections), previous immunosuppressive adverse reactions, compliance, and financial considerations are among the patient-specific factors considered in individualizing maintenance immunosuppression. Calcineurin inhibitors are generally a central component in most maintenance regimens, although calcineurin inhibitor–free immunosuppression remains a future goal because of the significant nephrotoxicity associated with these agents. Ideally, immunosuppression should be optimized to prevent acute rejection episodes and minimize the occurrence of chronic rejection.

CALCINEURIN INHIBITORS

2 Cyclosporine and tacrolimus are the two calcineurin inhibitors (CIs) currently used for most solid-organ transplant recipients. With the exception of heart transplant recipients (59%), more than 80% of transplant recipients receive tacrolimus as part of their immunosuppressive regimen.[1]

CLINICAL CONTROVERSY

Although calcineurin inhibitors are the mainstay of immunosuppressive protocols, some clinicians attempt to use calcineurin inhibitor–sparing protocols to avoid the significant adverse effects associated with calcineurin inhibitors. Others will delay the initiation of calcineurin inhibitors to avoid the dose-related adverse effects associated with their use during the early post-transplantation period.

Pharmacology/Mechanism of Action

Calcineurin inhibitors block T-cell proliferation by inhibiting the production of IL-2 and other cytokines by T cells (see Fig. 98–1). Cyclosporine and tacrolimus bind to unique cytoplasmic immunophilins cyclophilin and FK-binding protein-12 (FKBP12), respectively. The drug–immunophilin complex inhibits the action of calcineurin, an enzyme that activates the nuclear factor of activated T cells, which is, in turn, responsible for the transcription of several key cytokines necessary for T-cell activity, including IL-2. IL-2 is a potent growth factor for T cells and ultimately is responsible for activation and clonal expansion.

Pharmacokinetics

The calcineurin inhibitors are highly lipophilic compounds, with variable but generally low bioavailability of approximately 30% (range: 5% to 60%). Unlike tacrolimus, cyclosporine depends on bile for intestinal absorption, which lends to more interpatient and intrapatient variability. Liver recipients with a T-tube for diversion of bile may thus experience incomplete and erratic absorption of cyclosporine.

Because of the significant variability in absorption of cyclosporine, peak concentrations are reached within 2 to 6 hours of oral administration. To overcome the pharmacokinetic problems of cyclosporine, a microemulsion formulation was developed. Both forms are available commercially in the United States and are referred to as "cyclosporine, USP" and "cyclosporine, USP [MODIFIED]." The two formulations are not bioequivalent and should not be used interchangeably. The microemulsion formulation is self-emulsifying and forms a microemulsion spontaneously with aqueous fluids in the gastrointestinal tract, making it less dependent on bile for absorption. The result is a significantly greater rate and extent of absorption and decreased intraindividual variability in pharmacokinetic parameters. Bioavailability is enhanced owing to better dispersion and absorption and does not require bile excretion. The relative bioavailability of the microemulsion formulation is 60%. Peak concentrations are generally reached within 1.5 to 2 hours after oral administration. Tacrolimus, on the other hand, has a more predictable absorption pattern, reaching peak concentrations within 1 to 3 hours.

Following oral absorption, both cyclosporine and tacrolimus are highly protein bound. Ninety percent of cyclosporine is bound to lipoproteins in the blood. In contrast, 99% of tacrolimus is bound primarily to albumin and α_1-acid glycoprotein. Cyclosporine is distributed widely into tissue and body fluids, resulting in a large and variable volume of distribution, ranging from 3 to 5 L/kg. Because of the high concentration of FKBP12 that is found in red blood cells, tacrolimus is distributed primarily in the vasculature, with a volume of distribution of 0.8 to 1.9 L/kg. Both drugs are extensively metabolized by the cytochrome P450 3A4 (CYP3A4) system in both the gut and the liver, which accounts for both the poor bioavailability and numerous drug interactions (see Chap. 9).

Efficacy

The introduction of the calcineurin inhibitors significantly improved the outcomes of solid-organ transplantation in terms of patient and graft survival, with 1-year graft survival improving from 75 to 87% for cadaveric grafts.[17] Both cyclosporine and tacrolimus are currently approved for prophylaxis of organ rejection in kidney, liver, and heart transplantations. When compared with the standard formulation, the microemulsion formulation of cyclosporine has demonstrated equivalent or superior efficacy in kidney, liver, and heart transplantation recipients. Studies comparing tacrolimus with either formulation of cyclosporine as primary immunosuppression demonstrate equivalent efficacy between the two agents in all transplantation situations.

Monotherapy with calcineurin inhibitors has been described.[21] The avoidance of long-term corticosteroids is the primary advantage of calcineurin inhibitor monotherapy, whereas the primary disadvantage is the higher incidence of rejection. As a result, calcineurin inhibitors are rarely used as monotherapy.

Adverse Effects

Table 98–4 summarizes the adverse effects of calcineurin inhibitors, cyclosporine and tacrolimus, and other immunosuppressants. The nephrotoxic potential of both drugs is equal and is often related to the dose and duration of exposure. Neurotoxicity typically manifests as tremors, headache, and peripheral neuropathy; occasionally, however, seizures have been observed. Tacrolimus may be associated with an increased occurrence of neurologic complications compared with cyclosporine.

Cyclosporine appears to have a greater propensity to cause or worsen hypertension and hyperlipidemia compared with tacrolimus.[22–25] On the other hand, hyperglycemia is more common with tacrolimus than with cyclosporine but is often reversible when doses of tacrolimus and/or corticosteroids are reduced.[23] Cyclosporine is associated with cosmetic effects, such as hirsutism and gingival hyperplasia, which may be managed by converting

TABLE 98-4 Comparison of Common Adverse Effects of Maintenance Immunosuppressants

AZA	MMF	SIR	Steroids	CSA	TAC
Nausea, vomiting	Diarrhea, nausea	Hyperlipidemia	GI bleeding	Hyperlipidemia	Diarrhea, nausea

from cyclosporine to tacrolimus or by proper hygiene in patients who cannot be switched to tacrolimus. Tacrolimus, in contrast, has been reported to cause alopecia, which is usually self-limiting and reversible.

Calcineurin Inhibitor Nephrotoxicity

3 Two types of nephrotoxicity can occur with calcineurin inhibitors. Acute nephrotoxicity is frequently seen early and is dose dependent and reversible, but chronic nephropathy is more common. Clinical manifestations of calcineurin inhibitor nephrotoxicity include elevated serum creatinine and blood urea nitrogen levels, hyperkalemia, hyperuricemia, mild proteinuria, and a decreased fractional excretion of sodium. Calcineurin inhibitor nephrotoxicity is recognized as the leading cause of renal dysfunction following nonrenal solid-organ transplant.

The predominant mechanism for calcineurin inhibitor nephrotoxicity is renal vasoconstriction, primarily of the afferent arteriole, resulting in increased renal vascular resistance, decreased renal blood flow by up to 40%, reduced glomerular filtration rate by up to 30%, and increased proximal tubular sodium reabsorption with a reduction in urinary sodium and potassium excretion. A number of other mechanisms have been implicated, including changes in the renin–angiotensin–aldosterone system, prostaglandin synthesis, nitrous oxide production, sympathetic nervous system activation, and calcium handling.[26]

Measures to reduce calcineurin inhibitor nephrotoxicity include delaying administration immediately postoperatively in patients at high risk for nephrotoxicity (using alternative induction protocols including an IL-2 receptor antagonist or antilymphocyte globulin), monitoring calcineurin inhibitor trough blood levels and reducing the calcineurin inhibitor dosage if the vasoconstrictive effects are problematic, and avoiding other nephrotoxins (e.g., aminoglycosides, amphotericin B, and nonsteroidal antiinflammatory agents) when possible. Currently, no proven therapies consistently prevent or reverse the nephrotoxic effects of calcineurin inhibitors.

In patients who have received a kidney transplant, it is often difficult to differentiate calcineurin inhibitor nephrotoxicity from renal allograft rejection. Because the clinical features of acute renal allograft rejection and calcineurin inhibitor nephrotoxicity may overlap considerably, a renal biopsy is necessary to differentiate the two (Table 98–5). However, differentiating between chronic renal allograft rejection and calcineurin inhibitor nephrotoxicity may be more difficult because, in addition to clinical signs and symptoms, biopsy findings may also be similar.

Drug–Drug and Drug–Food Interactions

Drug interactions occur frequently with the calcineurin inhibitors because they are substrates for CYP3A4 and P-glycoprotein.[27–29] The most commonly administered drugs that are known to significantly alter cyclosporine and tacrolimus levels are highlighted in Table 98–6. Inhibitors of CYP3A4, such as diltiazem or erythromycin, can increase drug concentrations up to 82%, whereas drugs that induce CYP3A4 activity, such as phenytoin or rifampin, can decrease drug concentrations by 50%.[22] Some have taken advantage of these interactions by routinely prescribing CYP3A4 inhibitors to reduce the dosage and cost of calcineurin inhibitor therapy while maintaining the same therapeutic concentrations. This strategy seems more beneficial with cyclosporine than with tacrolimus.[30–32] While in vitro data suggest that drugs that increase the pH of the GI tract, such as magnesium-, aluminum-, or calcium-containing antacids, sodium bicarbonate, and magnesium oxide, can cause a pH-mediated degradation of tacrolimus by physically adsorbing tacrolimus in the GI tract, this has not been borne out in clinical studies.[33] Some clinicians suggest separating such compounds from tacrolimus administration by at least 2 hours to avoid any potential interaction.

Cyclosporine, and to a lesser extent, tacrolimus, are inhibitors of CYP3A4.[34] The inhibitory effects of cyclosporine and tacrolimus on CYP3A4 can be seen with weaker substrates, such as the HMG-CoA reductase inhibitors ("statins"). Concomitant administration of a calcineurin inhibitor with an HMG-CoA reductase inhibitor results in an increase in the HMG-CoA reductase inhibitor levels, which increases the risk of HMG-CoA reductase inhibitor adverse effects, most notably myopathy.[35] Patients should be monitored for clinical signs of myopathy when receiving HMG-CoA reductase inhibitors in combination with cyclosporine and tacrolimus.

TABLE 98-5 Differential Diagnosis of Acute Rejection and Cyclosporine or Tacrolimus Nephrotoxicity

	Nephrotoxicity in Renal Transplant Recipients	
	Acute Rejection	**CSA or TAC Nephrotoxicity**
History	Often <4 weeks postoperatively	Often >6 weeks postoperatively
Clinical presentation	Fever Hypertension Weight gain Graft swelling/tenderness Decreased daily urine volume	Afebrile Hypertension Graft nontender Good urine output
Laboratory biopsy	Rapid rise in serum Cr (0.3 mg/dL/day [27 micromol/L/day]) Normal CSA or TAC concentration Interstitial lymphocytic infiltrates	Gradual rise in serum Cr (>0.15 mg/dL/day [>13 micromol/L/day]) Elevated CSA or TAC concentration Interstitial fibrosis, tubular atrophy, glomerular thrombosis, arterial inflammation

Cr, creatinine; CSA, cyclosporine; TAC, tacrolimus.

Consistency in administration of the calcineurin inhibitors with regard to meals and food intake is important to sustain an effective concentration time profile. High-fat meals can enhance both plasma clearance and the volume of distribution of cyclosporine by more than 60%.[36] Food reduces the rate and extent of tacrolimus absorption, and a high-fat meal may further delay gastric emptying and reduce the maximum achieved serum concentration (C_{max}), and the area under the concentration–time curve (AUC).[31] Furocoumarins, such as quercetin, naringin, and bergamottin, found in grapefruit juice, are potent inhibitors of CYP3A4 and have increased both cyclosporine and tacrolimus concentrations significantly. The AUC and C_{max} of cyclosporine have been reported to be increased by more than 55% and 35%, respectively.[37]

Dosing and Administration

Initial oral cyclosporine doses range from 8 to 18 mg/kg per day administered every 12 hours. Higher doses of cyclosporine are used more commonly in two-drug regimens, whereas lower doses are part of triple-drug regimens. Oral tacrolimus doses range from 0.1 to 0.3 mg/kg per day given every 12 hours. If oral administration is not possible, both drugs can be administered intravenously at one third the oral dosage, to account for first-pass metabolism. A once-daily formulation of tacrolimus is currently available in Canada and Europe. After mg:mg conversion based on total daily dose, about one third of patients required downward dose adjustments on the basis of 24-trough concentrations.[38] The usual intravenous dose of cyclosporine is 2 to 5 mg/kg per day, given as a continuous infusion or as single or twice-daily injection. Intravenous tacrolimus doses range from 0.05 to 0.1 mg/kg per day and must be administered by continuous infusion. Children require higher doses to maintain therapeutic drug concentrations, up to 14 to 18 mg/kg per day for cyclosporine and 0.3 mg/kg per day for tacrolimus.

Therapeutic Drug Monitoring

Calcineurin inhibitor serum concentrations are measured routinely in an attempt to optimize therapy (Table 98–7). The most common and practical method for monitoring calcineurin inhibitors is by measuring trough blood concentrations. Radioimmunoassay (RIA) and fluorescence polarization immunoassay are the most commonly used methods to measure cyclosporine concentrations. Tacrolimus concentrations are most commonly measured by microparticle enzyme immunoassays or enzyme-linked immunoassays. Both drugs can be measured by high-performance liquid chromatography (HPLC), which is recognized as the reference procedure.[36] Therapeutic target ranges are assay specific because some quantitate parent plus metabolite concentration, while others only measure the parent compound. Thus, the target concentrations will be lower for the specific assays (HPLC) compared with nonspecific assays (RIA and microparticle enzyme immunoassays) by approximately 20% to 25%. The specific goal level for both drugs is dependent on transplant type, time after transplantation, concomitant immunosuppression, and transplantation center. One review of the role of tacrolimus in renal transplantation suggests that target 12-hour whole blood concentrations for tacrolimus are 15 to 20 ng/mL (15 to 20 µg/L; 18.6 to 24.8 nmol/L) (0 to 1 month after transplantation), 10 to 15 ng/mL (10 to 15 µg/L; 12.4 to 18.6 nmol/L) (1 to 3 months after transplantation), and 5 to 12 ng/mL (5 to 12 µg/L; 6.2 to 14.9 nmol/L) (>3 months after transplantation).[24] Serum drug concentrations should be measured frequently (daily or three times per week) following initiation of the drug and during the stabilization period after transplantation. As the time increases after transplantation, serum concentrations are measured less frequently, usually monthly.

Studies have revealed lack of predictive value of trough cyclosporine concentrations and rejection.[39] Alternative strategies, including AUC and peak concentration, have been suggested to better correlate with rejection.[36,39] Limited sampling techniques using two to five blood samples within the first 4 hours after an oral dose have been used. AUC levels > 4,400 mcg/L (> 3361 nmol/L) per hour correlate with a reduction in rejection.[36,39] Some transplantation

TABLE 98-7 Therapeutic Concentrations of Immunosuppressants by Various Methods

		Concentrations (ng/mL or mcg/L)	
Drug	**Sampling Medium**	**HPLC**	**RIA**
Cyclosporine	Whole blood	100–300	375–400
	Plasma	75–100	150–250
Tacrolimus	Whole blood	8–13	5–20
	Plasma		0.2–0.8

Sirolimus (without CIs)	Whole blood	15–25	20–30

CIs, calcineurin inhibitors; HPLC, high performance liquid chromatography; RIA, radioimmunoassay.

centers have adopted this strategy to manage cyclosporine levels because of the convenience of a single blood sample. The suggested therapeutic range for C_2 cyclosporine levels is 1,500 to 2,000 ng/mL (1,500 to 2,000 μg/L; 1248 to 1664 nmol/L) for the first few months after transplant and 700 to 900 ng/mL (700 to 900 μg/L; 582 to 749 nmol/L) after 6 to 12 months.[39] The predictive value of trough concentrations and rejection is also being questioned with tacrolimus. As a result, pharmacokinetic profiling with AUC and peak concentrations to determine alternative monitoring strategies are also being explored with tacrolimus.[39]

CORTICOSTEROIDS

4 Corticosteroids have been used since the beginning of the modern transplantation era. Despite their many adverse events, they continue to be a cornerstone of immunosuppression regimens in many transplant centers, with 40 to 70% of liver and kidney transplant patients, respectively, receiving corticosteroids at the time of hospital discharge.[1] The most commonly used corticosteroids in transplantation are methylprednisolone and prednisone.

Pharmacology/Mechanism of Action

Corticosteroids block cytokine activation by binding to corticosteroid response elements, thereby inhibiting IL-1, IL-2, IL-3, IL-6, γ-interferon, and tumor necrosis factor-α synthesis (see Fig. 98–1). Additionally, corticosteroids interfere with cell migration, recognition, and cytotoxic effector mechanisms.[40]

Pharmacokinetics

Prednisone is converted to active prednisolone in the body and has multiple effects on the immune system. Prednisone is very well absorbed from the GI tract and has a long biologic half-life, permitting daily administration.

Efficacy

Animal models of transplantation in the 1950s and 1960s used corticosteroids empirically in combination with azathioprine. Corticosteroids subsequently became a part of the immunosuppressive regimens used in the first human transplantations[41] and continue to be used in immunosuppressive protocols today. The efficacy of corticosteroids is irrefutable based on the decades of clinical experience. Systematic studies comparing corticosteroid-free immunosuppressive agent combinations with conventional therapy are difficult to perform because of the hundreds of potential combinations that now exist. However, recent studies of corticosteroid-free immunosuppressive agent combinations with newer, more specific immunosuppressants suggest that corticosteroids may in the future have less of a role in maintenance immunosuppression.[21,22]

Adverse Effects

Adverse effects of prednisone that occur in more than 10% of patients include increased appetite, insomnia, indigestion (bitter taste), and mood changes. Side effects that occur less often but which are seen with high doses or prolonged therapy include cataracts, hyperglycemia, hirsutism, bruising, acne, sodium and water retention, hypertension, bone growth suppression, and ulcerative esophagitis (see Table 98–4).

Drug–Drug and Drug–Food Interactions

Barbiturates, phenytoin, and rifampin induce hepatic metabolism of prednisone and thus decrease the effectiveness of prednisone. Prednisone decreases the effectiveness of vaccines and toxoids.[40]

Dosing and Administration

An intravenous corticosteroid, commonly high-dose methylprednisolone, is given at the time of transplantation. The dose of methylprednisolone is tapered rapidly and discontinued within days, and oral prednisone is initiated. Prednisone doses are tapered progressively over time, depending on the type of additional immunosuppression and organ function. It is preferable to administer corticosteroids between 7 AM and 8 AM to mimic the body's diurnal release of cortisol. While conversion to alternate-day regimens or complete withdrawal of prednisone in patients with stable post-transplantation courses has been used with success in some transplantation centers, corticosteroids are often continued for the entire life of the functional graft. The adverse effects of corticosteroids are summarized in Table 98–4.

The first-line therapy for the treatment of acute graft rejection is high-dose intravenous methylprednisolone (250 to 1,000 mg) daily for 3 days or oral prednisone (200 mg). Doses of oral prednisone are then tapered over 5 days to 20 mg/day. Prednisone should be taken with food to minimize GI upset. It is becoming a frequent practice to taper prednisone, with the goal of discontinuation over a period of months. Corticosteroids should never be discontinued abruptly; tapering should be gradual because of suppression of the hypothalamic–pituitary–adrenal axis. Corticosteroids slow the growth rates in children, prompting clinicians to use alternate-day dosing or to withhold corticosteroids until rejection occurs.

ANTIMETABOLITES

5 Antimetabolites have been used since the early days of transplantation because they prevent proliferation of lymphocytes. Azathioprine, long considered a part of the "gold standard" regimen with cyclosporine and corticosteroids, has largely been supplanted by mycophenolic acid derivatives as they are more specific in their effects on lymphocytes and have fewer side effects.

Mycophenolate

Mycophenolic acid (MPA) was first isolated from the *Penicillium glaucum* mold. Two formulations of MPA are currently available in the United States: mycophenolate mofetil is the morpholinoethyl ester of MPA, whereas mycophenolate sodium is available as an enteric-coated formulation of the sodium salt of MPA.

Pharmacology/Mechanism of Action The immunosuppressive effect of MPA is exerted through noncompetitive binding to inosine monophosphate dehydrogenase, the key enzyme responsible for guanosine nucleotide synthesis via the de novo pathway. Inhibition of inosine monophosphate dehydrogenase results in decreased nucleotide synthesis and diminished DNA polymerase activity, ultimately reducing lymphocyte proliferation.[42] The actions of MPA are more specific for T and B cells, which use only the de novo pathway for nucleotide synthesis (see Fig. 98–1). Other cells within the body have a salvage pathway by which they can synthesize nucleotides, making them less susceptible to the actions of MPA and thereby reducing, but not eliminating, the potential for the hematologic adverse effects seen with azathioprine. In addition to decreasing lymphocyte proliferation, MPA may also downregulate activation of lymphocytes.[43]

Pharmacokinetics Because MPA is unstable in an acidic environment, mycophenolate mofetil acts as a prodrug that is readily absorbed from the GI tract, after which it is rapidly and completely converted to MPA by first-pass metabolism. The enteric coating of mycophenolate sodium protects MPA from the acidic gastric pH and allows for MPA to be released directly into the small intestine for absorption. The absolute bioavailability of MPA when delivered

from mycophenolate mofetil and mycophenolate sodium is 94% and 72%, respectively. Peak concentrations of MPA are reached within 1 hour following administration of either preparation.

A total of 97% of MPA is bound to albumin in the blood. MPA is eliminated by the kidney and also undergoes glucuronidation in the liver to an inactive glucuronide metabolite (MPAG) that is excreted in the bile and urine. Enterohepatic cycling of MPAG can lead to deconjugation, thereby recirculating MPA into the bloodstream. The half-life of MPA is 18 hours.

Efficacy Currently, mycophenolate mofetil is approved for use in kidney, liver, and heart transplantations. Mycophenolate sodium was approved in 2004 for use in kidney transplantations only. Early studies comparing mycophenolate to azathioprine in patients receiving cyclosporine and corticosteroids demonstrated a statistically significant improvement in patient and graft survival at 1 and 3 years.[44] Subsequent studies have confirmed the efficacy of mycophenolate combined with tacrolimus. Mycophenolate has also demonstrated efficacy in the treatment of acute rejection.[45]

Mycophenolic acid derivatives are a key component of calcineurin inhibitor–sparing protocols. Although mycophenolate monotherapy has been investigated, patients experienced an unacceptable increase in rejection. Combination of mycophenolate with sirolimus, on the other hand, resulted in improved renal function with no change in acute rejection and patient and graft survival.[44]

Adverse Effects Unlike cyclosporine and tacrolimus, MPA is not associated with nephrotoxicity, neurotoxicity, or hypertension. The most common side effects are related to the GI tract, including nausea, vomiting, diarrhea, and abdominal pain (see Table 98–4), which occur with similar frequency during intravenous and oral therapy. Strategies to reduce GI symptoms include dose reduction, division of the total daily dose into three or four doses, administration with food, or titration upward from lower doses during initial therapy. Mycophenolate also has hematologic effects, such as leukopenia and anemia, particularly with higher doses. Recently, the rare but serious adverse events of progressive multifocal leukoencephalopathy (PML) and pure red cell aplasia have been reported. Because peripheral intravenous mycophenolate administration is associated with local edema and inflammation, central venous administration may be the preferred route.

Drug–Drug and Drug–Food Interactions Food has no effect on MPA AUC, but it delays the absorption and decreases MPA C_{max} by 40% and 33% when mycophenolate mofetil and mycophenolate sodium, respectively, are administered. Administration with aluminum- and magnesium-containing antacids or cholestyramine significantly decreases the AUC of MPA and should be avoided.[42] It has been suggested that administration of iron may produce similar results, but this has not been tested.

Acyclovir, commonly used in renal transplant recipients for the treatment and prevention of viral infections, competes with MPAG for renal tubular secretion. AUCs of both entities are increased with concomitant acyclovir and mycophenolate administration. No pharmacokinetic interaction with other antiviral agents has been demonstrated, but, there is potential for additive pharmacodynamic effects such as bone marrow suppression.

Decreased MPA trough concentrations have been reported when mycophenolate is administered with cyclosporine compared with those achieved when mycophenolate is given with tacrolimus or sirolimus. This interaction is most likely a result of cyclosporine interference with the enterohepatic recycling of MPAG, which results in decreased MPA concentrations.[46] To achieve equivalent MPA and MPAG serum concentrations, it may be necessary to administer higher doses of mycophenolate with cyclosporine compared to tacrolimus.

Dosing and Administration Mycophenolate mofetil is currently available in both oral and intravenous formulations. Although intravenous administration of equal doses closely mimics oral administration, the two cannot be considered bioequivalent.

Mycophenolate sodium is only available as an oral formulation. To optimize immunosuppression and minimize adverse effects, mycophenolate is administered in two divided doses given every 12 hours. The total daily dose for kidney and liver transplants is 2 g/day for mycophenolate mofetil and 1.44 g/day for mycophenolate sodium. A higher level of immunosuppression is required for heart transplants; thus for these patients a total daily dose of 3 g/day for mycophenolate mofetil and 2.16 g/day for mycophenolate sodium is recommended. The recommended pediatric dose is 600 mg/m^2 for mycophenolate mofetil and 400 mg/m^2 for mycophenolate sodium, in two divided doses.

While an increasing body of literature exists, the routine therapeutic drug monitoring of mycophenolic acid remains controversial. Plasma appears to be the most appropriate medium in which to measure MPA for therapeutic drug monitoring. Numerous studies have demonstrated a relationship between plasma MPA concentrations and improved clinical outcomes in patients receiving concomitant CIs and corticosteroids. Patients with trough MPA levels between 1.0 and 3.5 mcg/mL (1.0–3.5 mg/L; 3.1 to 10.9 micromol/L) experienced fewer significant complications. Free (fMPA) concentrations as opposed to total MPA concentrations have been suggested as the relevant measure, especially in patients with liver disease, hypoalbuminemia, and severe infection.[47] Trough concentrations may not be accurate in predicting total drug exposure during a 12-hour interval and thus AUC monitoring has been proposed as the most appropriate measure of MPA drug exposure to predict therapeutic outcomes.[47] Better outcomes are associated with MPA AUC levels of greater than 42.8 mcg/mL (42.8 mg/L; 134 micromol/L) per hour (by HPLC),[48] although a reference range of 30 to 60 mcg/mL (30 to 60 mg/L; 94 to 188 micromol/L) per hour has been proposed.[49] The correlation between MPA AUC levels and adverse effects is low. Further studies are required to determine the best means to evaluate MPA levels, the acceptable targets for each, and the appropriate strategy to monitor MPA levels.[48,49]

Azathioprine

Azathioprine, a prodrug for 6-mercaptopurine (6-MP), has been used as an immunosuppressant in combination with corticosteroids since the earliest days of the modern transplantation era. It is associated with substantial toxicities, however, and its use has dramatically declined with the availability of newer immunosuppressants.

Pharmacology/Mechanism of Action Azathioprine is an inactive compound that is converted rapidly to 6-MP in the blood and is subsequently metabolized by three different enzymes. Xanthine oxidase, found in the liver and GI tract, converts 6-MP to the inactive final end product, 6-thiouric acid. Thiopurine *S*-methyltransferase, found in hematopoietic tissues and red blood cells, methylates 6-MP to an inactive product, 6-methylmercaptopurine. Finally, hypoxanthine-guanine phosphoribosyltransferase is the first step responsible for converting 6-MP to 6-thioguanine nucleotides (6-TGNs), the active metabolites, which are incorporated into nucleic acids, ultimately disrupting both the salvage and de novo pathways of DNA, RNA, and protein synthesis. This process is toxic to the cell and renders the cell unable to proliferate (see Fig. 98–1). Eventually, 6-TGNs are catabolized by xanthine oxidase and thiopurine *S*-methyltransferase to inactive products.[50]

Pharmacokinetics Oral bioavailability of azathioprine is approximately 40%. Metabolism of 6-MP is primarily by xanthine oxidase to inactive metabolites, which are excreted by the kidneys. The half-life of azathioprine, the parent compound, is very short,

approximately 12 minutes. The half-life of 6-MP is longer, ranging from 0.7 to 3 hours. However, it is the activity of the 6-TGNs that determines the pharmacodynamic half-life of the drug. The half-life of 6-TGNs has been estimated to be 9 days.[50]

Adverse Effects Dose-limiting adverse effects of azathioprine are often hematologic (see Table 98–4). Leukopenia, anemia, and thrombocytopenia can occur within the first few weeks of therapy and can be managed by dose reduction or discontinuation of azathioprine. Other common adverse effects include nausea and vomiting, which can be minimized by taking azathioprine with food. Alopecia, hepatotoxicity, and pancreatitis are less common adverse effects of azathioprine and are reversible on dose reduction or discontinuation.

Drug–Drug and Drug–Food Interactions The xanthine oxidase inhibitor allopurinol can increase azathioprine and 6-MP concentrations by as much as fourfold. The metabolic pathways shift to favor production of 6-TGNs, which ultimately results in increased bone marrow suppression and pancytopenia. Doses of azathioprine should be reduced by 50% to 75% when allopurinol is added. Additional clinically significant drug interactions include other bone marrow–suppressing agents such as ganciclovir, trimethoprim-sulfamethoxazole, and sirolimus, and other drugs that irritate the GI tract.

Dosing and Administration Initial doses of azathioprine are 3 to 5 mg/kg per day intravenously or orally. Individualization to maintain the white blood cell count between 3,500 and 6,000 cells/mm (3.5 and 6.0 × 10^9/L) may be accomplished in some with doses as low as 0.25 mg/kg per day.[2] Patients are often instructed to take azathioprine in the evening when initiating or titrating therapy to allow for dose adjustments based on morning determinations of their white blood cell count.

MAMMALIAN TARGET OF RAPAMYCIN INHIBITORS

6 Two mammalian target of rapamycin (mTOR) inhibitors have been approved in the United States for use in transplantation. Sirolimus, also known as rapamycin, is an immunosuppressive macrolide antibiotic that is structurally similar to tacrolimus, and is effective in reducing the risk of acute rejection. Sirolimus is thought to have potential to reduce chronic rejection, but this remains to be proven. Everolimus was approved in 2009.

Pharmacology/Mechanism of Action Sirolimus and everolimus both bind to FKBP12, forming a complex that binds to mTOR, which inhibits the response to cytokines (see Fig. 98–1). IL-2 stimulates mTOR to activate kinases that ultimately advance the cell cycle from G1 to the S phase. Thus they reduce T-cell proliferation by inhibiting the cellular response to IL-2 and progression of the cell cycle. To this end, this class is also referred to as proliferation signal inhibitors.[51,52]

Pharmacokinetics Bioavailability after oral administration is low for both, only 15–16%, with peak concentrations being reached within 1 to 2 hours for sirolimus and 0.5–4 hours for everolimus.[51,52] Both have large volumes of distribution, 5.6–16.7 L/kg for sirolimus and about 110 L for everolimus. Both are metabolized primarily by CYP3A4 both in the gut and in the liver. Likewise, both are also substrates for P-glycoprotein. The half-life for sirolimus is reported to be 60 hours but can be as long as 110 hours in patients with liver dysfunction, while that of everolimus is much shorter, 18–35 hours.[51,52]

Efficacy Sirolimus is only approved for the prevention of rejection in kidney transplant recipients when given in combination with corticosteroids and cyclosporine or after withdrawal of cyclosporine in patients with low to moderate immunologic risk. Sirolimus has also been demonstrated to be effective in combination with tacrolimus or mycophenolate in kidney transplants, with patient survival rates >99% and graft survival rates >96%.[51] Combination therapy with sirolimus and mycophenolate can be used to avoid the use of calcineurin inhibitors and decrease the risk of nephrotoxicity. Everolimus was approved for use in renal transplantation in combination with basiliximab, cyclosporine, and corticosteroids.

Two Phase III trials evaluated the use of sirolimus in kidney transplants. All patients in both studies received cyclosporine and corticosteroids and were randomly assigned to one of three groups: (a) sirolimus in a fixed dose—a 6-mg loading dose followed by 2 mg daily; (b) a 15-mg loading dose followed by 5 mg daily; or (c) azathioprine in the U.S. trial or placebo in the global trial. The results of both studies showed similar patient and graft survival in all groups at 12 months but lower rates of acute rejection in the sirolimus arms compared with azathioprine and placebo.[51]

Early cyclosporine withdrawal has been studied in patients receiving sirolimus-based immunosuppressive protocols. Patients receiving sirolimus who did not have a recent or severe rejection episode and adequate renal function 3 months after transplant were enrolled. Patients were randomly assigned to continue triple-drug therapy with sirolimus (adjusted to trough concentrations of greater than 5 ng/mL), cyclosporine, and corticosteroids or double-drug therapy with sirolimus (adjusted to trough concentrations of 20 to 30 ng/mL) and corticosteroids. Rejection occurred in 5.6% of patients after discontinuation of cyclosporine, with no difference in graft survival. Long-term follow-up (2 years) showed improved renal function and blood pressure without an increase in acute rejection or graft loss in patients who discontinued cyclosporine.[51]

Everolimus in combination with reduced doses of cyclosporine (target 100–200ng/ml for the first month post transplant) and steroids was comparable to mycophenolic acid (1.44 g/day) in combination with standard cyclosporine doses (target 100–200 ng/mL in the first month) and steroids in terms of biopsy-proved rejection, graft loss, or death. There was no difference in estimated GFR at 12 months. Similarly, a trial of high-dose everolimus/low-dose CSA (target 8—12 ng/mL vs. 3—8 ng/mL) showed no difference in 6- and 12-month GFR between the two groups despite differences in CSA exposure.[53]

Currently, because the safety and efficacy of sirolimus and everolimus have not been established in liver or lung transplants, it is recommended that their use be avoided in these populations immediately following transplant. In contrast, limited data on the use of sirolimus in heart transplantation indicate benefit in reversing acute rejection in patients who do not respond to antilymphocyte therapy.[51] Furthermore, mTOR inhibitors may slow the progression of vasculopathy, which may have an impact on chronic rejection and long-term patient survival after heart transplantation.[19]

Adverse Effects Both everolimus and sirolimus are associated with dose-related myelosuppression. Thrombocytopenia is usually seen within the first 2 weeks of sirolimus therapy but generally improves with continued treatment; leukopenia and anemia are also typically transient.[51,52] Sirolimus trough serum concentrations greater than 15 ng/mL have been correlated with thrombocytopenia and leukopenia.[51] Hypercholesterolemia and hypertriglyceridemia are also common in patients receiving everolimus or sirolimus. It is postulated that the mechanism of this adverse effect is related to an overproduction of lipoproteins or inhibition of lipoprotein lipase. Peak cholesterol and triglyceride levels are often seen within 3 months of sirolimus initiation but usually decrease after 1 year of therapy and can be managed by reducing the dose, discontinuing sirolimus, or initiating therapy with an HMG-CoA reductase inhibitor or fibric acid derivative. One study suggests that the

dyslipidemia associated with sirolimus is not a major risk factor for early cardiovascular complications following kidney transplantation.[54] Delayed wound healing and dehiscence could be a result of inhibition of smooth muscle proliferation and intimal thickening.[51] Mouth ulcers also have been reported with sirolimus, more commonly with the oral solution, possibly as a direct effect of the drug or secondary to activation of herpes simplex virus.[55] Reversible interstitial pneumonitis has been described in kidney, liver, and heart–lung transplantation recipients.[51] Other adverse effects reported with sirolimus include increased liver enzymes, hypertension, rash, acne, diarrhea, and arthralgia (see Table 98–4).

Drug–Drug and Drug–Food Interactions The major metabolic pathway for everolimus and sirolimus is CYP3A4; thus, the drug interactions mediated by induction or inhibition of the CYP3A4 enzyme system are similar to those seen with cyclosporine and tacrolimus (see Table 98–5). Administration of the microemulsion formulation of cyclosporine with sirolimus significantly increases the AUC and trough sirolimus levels. The same is not seen with the standard formulation of cyclosporine. Conversely, cyclosporine concentrations and AUC are also increased when it is given concomitantly with sirolimus. The mechanism is proposed to be competitive binding to CYP3A4 and P-glycoprotein.[51,52] It is recommended that patients separate the dose of sirolimus and cyclosporine by 4 hours to minimize the interaction.[51] Concomitant administration of tacrolimus does not affect sirolimus levels.[51] Although everolimus AUC was increased by the administration of a single dose of cyclosporine modified, no specific recommendations for dose timing are given. It should be expected, however, that any changes in CSA dose may also necessitate a modification of everolimus dose and increased therapeutic drug monitoring is indicated.[52]

As with cyclosporine and tacrolimus, grapefruit juice increases sirolimus levels. Administration of sirolimus with a high-fat meal is associated with a delayed rate of absorption, decreased C_{max}, and increased AUC, indicating an increased drug exposure, whereas the half-life remains unchanged.[51] Conversely, administration of everolimus with a high-fat meal decreases both C_{max} and AUC.[52]

Dosing and Administration A fixed sirolimus dosing regimen is approved for concomitant use with cyclosporine that includes a loading dose of 6 or 15 mg followed by 2 or 5 mg daily, respectively. Therapeutic monitoring of sirolimus is advocated using whole-blood concentrations measured by HPLC, which is specific for the parent compound (see Table 98–7). For everolimus a starting dose of 0.75 mg twice daily is indicated in regimens that contain cyclosporine, corticosteroids, and basiliximab. Target concentrations are 3—8 ng/ml.

Antibody Agents

7 Both polyclonal and monoclonal antibody preparations are used in transplantation. These agents can also be differentiated by their level of specificity, that is, particular receptor(s), or their downstream affects. In the following text the agents are discussed as those that deplete lymphocytic cell lines (depleting antibodies) and those that generally bind to specific receptors but do not result in depletion of the cell to which they bind.

■ DEPLETING ANTIBODIES

Antithymocyte Globulin

Two antithymocyte globulins are available in the United States: ATG (Atgam, Pfizer, New York, NY), an equine polyclonal antibody, and RATG (Thymoglobulin, Genzyme, Cambridge, MA), a rabbit polyclonal antibody. The rabbit preparation is less immunogenic and may have other advantages over the equine preparation. Both ATG and RATG are often used as induction therapy to prevent acute rejection. In 2006 40–60% of kidney transplant recipients received RATG induction, for example.[1]

Pharmacology/Mechanism of Action Because of their polyclonal antibody nature, both ATG and RATG exert their immunosuppressive effect by binding to a wide array of lymphocyte receptors (CD2, CD3, CD4, CD8, CD25, and CD45). Binding of ATG or RATG to the various receptors results in complement-mediated lysis and subsequent lymphocyte depletion. While T cells are the major lymphocytic target for the compounds, other blood cell components such as B cells and other leukocytes are also affected (see Fig. 98–1). Damaged T cells are subsequently removed by the spleen, liver, and lungs.

Pharmacokinetics ATG is poorly distributed into lymphoid tissue and binds primarily to circulating lymphocytes, granulocytes, and platelets. The terminal half-life of ATG is 5.7 days. RATG has a volume of distribution of 0.12 L/kg, and its terminal half-life in renal transplant recipients is significantly longer than ATG at 30 days.[56] Peak plasma concentrations are reached after 5 to 7 days of ATG or RATG infusions. Antiequine antibodies can form in up to 78% of patients who are receiving ATG therapy. Similarly, antirabbit antibodies have been reported in up to 68% of patients who are receiving RATG therapy. The effects of preformed antibodies on the efficacy and safety of these preparations have not been studied adequately.

Efficacy ATG and RATG are used most commonly for the treatment of acute allograft rejection or as induction therapy to prevent acute rejection. ATG is currently approved for both indications in kidney transplants. RATG is approved only for the treatment of acute allograft rejection in kidney transplantations. Both drugs have been studied extensively for both indications.

Use of RATG as part of quadruple therapy in liver transplantation is associated with similar rates of patient and graft survival and acute rejection compared with dual therapy. In kidney transplant RATG was associated with improved graft survival at 5 years as compared with equine ATG. Quadruple-drug therapy results in similar rates of patient and graft survival and malignancy in heart transplantations, but a significantly lower rate of acute rejection and infection episodes is seen at 1 year compared with triple-drug therapy. Cytomegalovirus (CMV) is an adverse effect of this strategy, but recent data indicate that routine prophylaxis is successful in this setting.[57]

Adverse Effects Most adverse effects reported with ATG and RATG are related to the lack of specificity for T cells owing to their polyclonal nature. Dose-limiting myelosuppression (leukopenia, anemia, and thrombocytopenia) occurs frequently. Other adverse effects include anaphylaxis, hypotension, hypertension, tachycardia, dyspnea, urticaria, and rash. Serum sickness is seen more frequently with ATG than with RATG. Nephrotoxicity has been reported but is rare in the absence of serum sickness. Infusion-related febrile reactions are most common with the first few doses and can be managed by premedicating the patient with acetaminophen, diphenhydramine, and corticosteroids. Finally, as with any immunosuppressive agent, ATG and RATG are associated with an increased risk of infections, particularly viral infections, and malignancy.

Drug–Drug and Drug–Food Interactions Administration of ATG or RATG can interfere with the immune response to live vaccines, such as varicella vaccine. If a live vaccine is administered within 2 months of receiving one of these immunoglobulins, protection may not be conferred.

Dosing and Administration ATG doses range from 10 to 30 mg/kg per day as a single dose for 7 to 14 days. RATG is a more potent compound and is administered at doses of 1 to 1.5 mg/kg

per day as a single dose for 7 to 14 days for acute rejection or for 5 to 10 days for induction of immunosuppression. Although literature reports now support peripheral administration of both agents, it is recommended that both ATG and RATG be administered through a central line or through a high-flow vein with an in-line 0.22-micron filter over at least 4 hours to minimize phlebitis and thrombosis whenever possible.[57,58]

Muromonab-CD3

Pharmacology/Mechanism of Action OKT3 is a murine monoclonal antibody to the CD3 receptor on mature human T cells (see Fig. 98–1). Administration of OKT3 results in both T-cell depletion and functional alteration. Cells reappear after a few days but bear no CD3 receptors. After cessation of OKT3 therapy, T-cell function normalizes in a week.[59]

Pharmacokinetics OKT3 has a volume of distribution of 6.5 L and half-life of about 18 hours. Concentrations above 0.9 mcg/mL (0.9 mg/L) are considered therapeutic. An OKT3 concentration of 0.8 mcg/mL (0.9 mg/L) or greater in combination with a CD3+ T-cell count of <25 cells/mL ($<25 \times 10^6$/L) is also a reasonable therapeutic target. If CD3 levels begin to rise, this may signify the presence of antimurine antibodies antagonizing the actions of OKT3. Administration of mycophenolate mofetil has been suggested to reduce the formation of antimurine antibodies during OKT3 administration. Although T-cell depletion is achieved within minutes of administration, resolution of rejection takes 3 to 4 days.

Efficacy OKT3 has been used as induction therapy at doses of 5 mg/day for 7 to 14 days. OKT3 can be used safely and successfully as an acute rejection therapy in patients who have undergone previous OKT3 induction.[59] Specifically, these studies confirm that the presence of low anti-OKT3 antibody titers (≤1:100) does not preclude successful retreatment with OKT3 for rejection. Aside from intestinal transplantation, OKT3 is usually reserved for treatment of corticosteroid-resistant rejection.

Adverse Effects OKT3 administration is associated with a cytokine release syndrome including fever, chills, rigors, pruritus, and alterations in blood pressure, which is most common with the first dose. Methylprednisolone, acetaminophen, and diphenhydramine are commonly administered as premedications to prevent or minimize the severity of this syndrome. Other adverse effects include capillary leak syndrome and pulmonary edema, especially in fluid-overloaded patients. Aseptic meningitis, another potential complication of OKT3 therapy, warrants discontinuation of OKT3. Other adverse effects include encephalopathy, nephrotoxicity, infection, and post-transplantation lymphoproliferative disorder.[40]

Drug-Drug and Drug-Food Interactions No drug or food interactions have been reported with OKT3.

Dosing and Administration OKT3 should be filtered with a 0.2- to 0.22-micron filter and then administered as an intravenous push over 1 minute. The dose of OKT3 is usually 5 mg/day for 5 to 14 days.[59] Vital signs should be assessed frequently during the first few doses, and it is advisable to have a physician present for the first dose. A high proportion of patients treated with OKT3 form antibodies to one of the components of OKT3 and may not be able to receive or adequately respond to retreatment.[59] The dosages of other immunosuppressant drugs may be decreased to avoid over-immunosuppression during OKT3 therapy.

Alemtuzumab

Alemtuzumab is approved for use in B-cell chronic lymphocytic leukemia. However, its effects on depleting both T and B lymphocytes make it useful in solid-organ transplants. While alemtuzumab is not FDA approved for solid organ transplantation, it is increasingly recognized as a viable therapeutic option. In 2006 10% of kidney transplant patients received alemtuzumab at the time of transplant.[1]

Pharmacology/Mechanism of Action Alemtuzumab is a humanized monoclonal antibody against the CD52 surface antigen found on both T and B lymphocytes, as well as macrophages, monocytes, eosinophils, and natural killer cells. When alemtuzumab binds to the CD52 surface antigen, antibody-dependent lysis occurs, which removes both T and B lymphocytes from the blood, bone marrow, and organs, resulting in complete lymphocyte depletion.[60]

Pharmacokinetics The pharmacokinetics of alemtuzumab in solid-organ transplantation patients have not been investigated. Data from patients with B-cell chronic lymphocytic leukemia indicate that the volume of distribution of alemtuzumab after repeated dosing is 0.18 L/kg. The mean half-life after the first 30 mg dose was 11 hours, but increased to 6 days after 12 weeks of therapy. The extrapolation of these data to solid-organ transplantation is difficult because of the differences in dosing strategies (single or double doses in solid-organ transplantation versus weekly to thrice weekly dosing in B-cell chronic lymphocytic leukemia). One or two doses of alemtuzumab result in complete and prolonged lymphocyte depletion. Following administration, B lymphocyte counts return to normal within 3 to 12 months. T lymphocytes, however, remain depressed for as long as 3 years following administration.[60,61]

Efficacy Recent data suggest that alemtuzumab is effective as induction therapy for the prevention of acute rejection in kidney, liver, pancreas, intestinal, and lung transplants.[60] Additionally, alemtuzumab has been used to successfully treat acute rejection following transplantation and is effective for corticosteroid- and antibody-resistant rejection.[61,62] The most promising role of alemtuzumab in solid-organ transplantation is its use in corticosteroid-sparing protocols, which allow for calcineurin inhibitor monotherapy following transplantation. Tacrolimus appears to be the optimal calcineurin inhibitor to use for monotherapy immunosuppression in patients who receive alemtuzumab induction.

Adverse Effects Adverse effects of alemtuzumab are primarily infusion related, hematologic, and infectious. Infusion-related reactions include rigors, hypotension, fever, shortness of breath, bronchospasms, and chills. The potential for developing these reactions can be reduced by administering premedications such as acetaminophen, corticosteroids and diphenhydramine or by administering smaller doses and escalating the dose gradually. Hematologic effects include pancytopenia, neutropenia, thrombocytopenia, and lymphopenia.

Drug–Drug and Drug–Food Interactions No drug or food interactions have been reported with alemtuzumab.

Dosing and Administration Several dosing regimens have been proposed for alemtuzumab in solid-organ transplantation. The most common dosing strategy for alemtuzumab is 30 mg as a single dose; some centers administer a second dose 1 to 5 days after transplantation.[60] Other studied dosing strategies include 0.3 mg/kg per dose, as a single- or multiple-dose regimen, and, finally, two 20-mg doses given on the day of transplantation and the first postoperative day.[62]

NONDEPLETING ANTIBODIES

Interleukin-2 Receptor Antagonists

Basiliximab, a chimeric monoclonal antibody (25% murine) is the only available IL-2 receptor antagonist in the United States. Daclizumab, a humanized monoclonal antibody (90% human, 10% murine) was withdrawn in 2009. Daclizumab contains a greater proportion of human sequences, making it theoretically less

immunogenic. The percentage of murine component determines the antibody's affinity for the epitope. Consequently, the chimeric antibody basiliximab has a higher affinity than daclizumab.[63]

Pharmacology/Mechanism of Action Both basiliximab and daclizumab exert their immunosuppressive effect by specifically binding to the α-chain (CD25) on the surface of activated T lymphocytes (see Fig. 98–1). Binding of either basiliximab or daclizumab to the IL-2 receptor prevents IL-2-mediated activation and proliferation of T cells, a critical step in clonal expansion of T cells and the development of allograft rejection. Saturation of the IL-2 receptor occurs rapidly and confers an immunosuppressive effect immediately.[63]

Pharmacokinetics Most of the pharmacokinetic data available for both basiliximab and daclizumab are in renal transplantation patients. Caution must be used when extrapolating these data to nonrenal transplantation recipients. The volume of distribution is approximately 5.3 L for daclizumab and 8 L for basiliximab. Basiliximab and daclizumab saturate CD25 in vivo at serum concentrations of 0.2 and 1 mg/L or greater, respectively.[64] The terminal half-life of daclizumab is about 20 days in renal transplantation patients compared with 3 to 4 days in bone marrow transplant recipients. Basiliximab has a shorter half-life of approximately 7 days in renal transplant recipients. Clearance of both drugs is increased in patients who have received a liver transplant, primarily as a consequence of drainage of ascites. It is recommended that patients with greater than 10 L of ascites receive an additional dose of basiliximab on postoperative day 8.[65] Therapeutic concentrations of daclizumab range from 5 to 10 mg/L.

Efficacy Both basiliximab and daclizumab are approved for use in kidney transplantation in combination with cyclosporine and corticosteroids, although induction therapy has also been studied extensively in liver and heart transplantation recipients. In 2006 28% of kidney and heart transplant recipients received an IL-2 receptor antagonist at the time of transplant.[1] A meta-analysis of daclizumab and basiliximab in renal transplantation concluded that IL-2 receptor antagonists reduced the risk of rejection significantly with no increases in graft loss, infectious complications, malignancy, or death.[66] Similar results were seen in liver and heart transplantation.[65]

IL-2 receptor antagonists offer a reasonable addition to calcineurin inhibitor– or corticosteroid-sparing protocols. While calcineurin inhibitor therapy can not be completely avoided in most cases,[64] IL-2 receptor antagonists allow for delayed use or reduced doses of calcineurin inhibitors, thus minimizing the risk of nephrotoxicity in the early post-transplantation period. Similar rates of rejection and corticosteroid-resistant rejection were seen in patients with DGF who received an IL-2 receptor antagonist in conjunction with lower tacrolimus doses compared with patients without DGF who received standard tacrolimus doses and no IL-2 receptor inhibitor induction.[63]

Adverse Effects Few adverse effects have been reported with basiliximab and daclizumab. In contrast to lymphocyte-depleting agents, basiliximab and daclizumab have not been associated with infusion-related reactions. However, since the marketing of basiliximab, an increased number of hypersensitivity reactions have been reported. Of note, only one patient developed anti-idiotypic antibodies to the murine portion during clinical trials.[65] The manufacturer of basiliximab reported an increase in mortality in a placebo-controlled trial, which was associated with an increase in severe infections. No increased risk of malignancy has been reported.

Drug–Drug and Drug–Food Interactions Reports of increased cyclosporine and tacrolimus levels in patients receiving concomitant basiliximab were recently published.[63,64] Both authors hypothesized a potential interaction with the cytochrome P450. No drug interactions have been reported with daclizumab.

Dosing and Administration Basiliximab is administered as two 20-mg intravenous doses, intraoperatively and again on postoperative day 4. Basiliximab is compatible with both 0.9% sodium chloride and 5% dextrose and can be administered either centrally or peripherally over 20 to 30 minutes in a volume of 50 mL. This regimen results in saturation of the IL-2 receptor for 30 to 45 days. The approved daclizumab dosing regimen for renal transplantation is 1 mg/kg every 2 weeks from the time of transplant for a total of 5 doses. Daclizumab should be diluted in 50 mL of sterile 0.9% sodium chloride and administered peripherally or centrally over 15 minutes. This regimen saturates the IL-2 receptors for approximately 90 to 120 days after renal transplantation.[64] Alternative dosing regimens have been proposed for daclizumab in combination with tacrolimus, mycophenolate, and corticosteroids: 1 mg/kg every 2 weeks for 5 doses, 2 mg/kg every 2 weeks for 2 doses, or 2 mg/kg on day 0 followed by 1 mg/kg on day 5.[64,67]

Investigational Agents

Belatacept Belatacept, derived from abatacept, is a selective costimulation blocker that binds costimulatory ligands (CD80 and CD86) on antigen presenting cells. This prevents interaction of CD80 and 86 with CD28 on T cells thus inhibiting T-cell activation. Belatacept is still in the investigational phase of development.[68]

In a phase II evaluation of two dosing strategies of belatacept versus cyclosporine in combination with basiliximab, mycophenolate mofetil, and corticosteroids in 218 renal transplant patients there was no difference in the rates of acute cellular rejection at 6 months. However, in patients treated with belatacept, GFR as measured by iohexol clearance was significantly higher than cyclosporine-treated patients at 12 months. Chronic allograft nephropathy as detected by protocol biopsy was also significantly lower in the belatacept groups. Belatacept has been well tolerated. At 12-month follow-up no adverse effects were reported in greater number in the belatacept groups. Cyclosporine–treated patients experienced more hypertension and hyperlipidemia.[68]

Belatacept was administered by intermittent intravenous infusion. While this improves compliance in some patients, the inability to reverse immunosuppression in patients with life-threatening infections may hinder acceptance.[68] Ongoing trials will define dosing strategies and place in transplant therapy, if any, for belatacept.

Bortezomib Bortezomib, a proteosomal inhibitor that is FDA approved for the treatment of multiple myeloma, has recently been used in the treatment of AMR. Everly and colleagues reported the use of bortezomib in six renal transplant recipients with AMR and concurrent ACR. In this small series rejection was reversed, donor-specific antibody levels decreased, and renal allograft function improved. All patients received four doses of intravenous bortezomib 1.3mg/m^2. Side effects included gastrointestinal, thrombocytopenia, and paresthesias.[69] Bortezomib may also be effective in preventing the development of AMR. Trivedi and colleagues used four doses of bortezomib 1.3 mg/ m^2 in a group of patients with elevated anti-HLA antibody levels in the absence of acute rejection after transplantation. Patients also received methylprednisolone and treatment with plasmapheresis. Antibody elevations resolved in 9 of 11 patients in 14 to 87 days. The incidence of rejection was not reported.[70]

Rituximab Rituximab is a humanized monoclonal antibody against the CD20 receptor found on B cells. While it is FDA approved for non-Hodgkin lymphoma and rheumatoid arthritis, it has also been used in various aspects of transplant medicine, including treatment of AMR and suppression of alloantibodies prior to transplantation.[71] The optimal dose of rituximab in transplantation has not been defined.

TABLE 98-8 Factors Negatively Affecting Allograft and Patient Survival

	Kidney	Liver	Heart
Donor factors	Decreased HLA matching Increased age Increased serum creatine Cardiac instability Prolonged ischemia time History of hypertension	Size mismatch Age (youngest, oldest)	Size mismatch Increased age Prolonged ischemia time
Recipient factors	Age <15, >50 years Retransplantation African race Elevated PRA Multiparous women Poor drug compliance	Increased age Retransplantation African race ICU pretransplant ABO blood type Poor drug compliance	Age <5, >60 years ICU pretransplant Mechanical ventilation LVAD IABP Poor drug compliance

HLA, human leukocyte antigens; IABP, intraaortic balloon pump; LVAD, left ventricular assist device; PRA, panel of reactive antibodies.

EVALUATION OF THERAPEUTIC OUTCOMES

8 The success of transplantation can be measured in terms of length of graft and patient survival or quality of life. Several donor and recipient factors that have an impact on graft and patient survival have been identified (Table 98–8). The greatest risk to short-term graft survival is acute rejection. Routine surveillance of appropriate biochemical markers and serum drug concentrations are essential to minimize the potential for acute rejection. These parameters should be assessed daily to weekly for the first 1 to 3 months after transplantation. Monitoring should include complete blood counts, serum electrolyte concentrations, serum creatinine and blood urea nitrogen concentrations, and the appropriate serum drug concentrations. Liver function tests should also be evaluated using the same schedule in liver transplantation recipients. Routine biopsies are necessary to monitor for acute rejection in heart transplantation recipients. As the time after transplantation increases, the frequency of monitoring decreases. Once 3 months have elapsed after transplantation, monitoring of these parameters can be reduced to biweekly or monthly for most patients.

Long-term graft survival is limited by chronic rejection. Overall survival rates for solid-organ transplantations are described in terms of half-life, or the time after transplantation at which only 50% of transplanted organs are still functioning. Estimated half-lives for kidneys are 26.9 years for HLA-identical grafts and 12.2 and 10.8 years, respectively, for grafts from a sibling or parent who are 1-haplotype matches. The estimated half-life for HLA-matched grafts was 17.3 years while a markedly lower value of 7.8 years has been noted with mismatched kidneys.[17] The overall median patient survival time for heart transplantation recipients is 9.8 years, but in these patients surviving the first year after transplantation, the median survival increases to 12 years.[1] The highest rate of mortality occurs within the first year after liver transplantation due to the risks of surgery and early postoperative complications. Table 98–9 depicts a typical post-transplantation laboratory monitoring plan.

ECONOMIC CONSIDERATIONS

Renal transplant has been shown to be the most cost-effective means of chronic renal replacement therapy.[72] The degree to which patients remain eligible for Medicare coverage after transplantation impacts kidney allograft survival, presumably secondary to effects on medication availability and compliance. Lifetime extension of Medicare-covered immunosuppression has been associated with improved allograft survival in low-income recipients, with a relative reduction in graft failure rates of 21–27%. In patients who do not otherwise qualify due to age or disability, Medicare currently only provides coverage for immunosuppression for the first 3 years after transplant.[73] Noncompliance has been associated with a sevenfold increased risk of graft failure.[74]

The assessment of the economic impact of liver and heart transplantation is complex. Unlike renal transplantation, liver and heart transplantation is lifesaving. However, there are factors that impact the overall cost of liver transplant that may impact patient selection. Patients awaiting transplant at home, for example, cost less than those who were hospitalized ($114,000 vs $154,000 and $211,000 for ward and ICU care, respectively). Malnutrition and renal impairment have also been shown to increase costs associated with liver transplant by 38% and 39%, respectively.[75] It has been estimated that the total charges for a given heart transplant were approximately $300,000 for the first year, with an additional $20,000 per year of follow-up. If cardiac-assist devices become a viable long-term therapeutic option for end-stage heart failure (estimates of $100,000–$500,000 per year), this will have a significant therapeutic as well as economic impact.[76]

TABLE 98-9 Laboratory Monitoring after Transplantation as a Function of Time Post-Transplant

	1–2 Weeks	1 Month	2–4 Months	4–12 Months	>12 Months
SCr/BUN	Daily	1–2 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Chemistries[a]	Daily	1–2 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Liver function tests[b]					
Kidney or heart recipient	Once	Once	Monthly	Every 1–3 months	Every 1–3 months
Liver recipient	Daily	1–3 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Immunosuppressant level	Daily	1–2 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Complete blood count[c]	Daily	1–2 times per week	Every 1–2 weeks	Monthly	Every 1–2 months
Lipid panel[d]	Once	Every 3 months	Every 3 months	Every 3 months	Every 3 months
HbA_{1c}	Once	Every 3 months	Every 3 months	Every 3 months	Every 3 months

BUN, blood urea nitrogen; HbA_{1c}, hemoglobin A1c; SCr infusion, serum creatinine.
[a]Chemistries include sodium, potassium, chloride, CO_2 content, magnesium, calcium, phosphorus, and blood glucose.
[b]Liver function tests include total bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), gamma glutamyl transpeptidase (GGTP), alkaline phosphatase.
[c]Complete blood count includes white blood cells (WBC), red blood cells (RBC), platelets, and/or differential.
[d]Lipid panel includes total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), triglyceride, and/or very low-density lipoprotein (VLDL).

CLINICAL CONTROVERSY

Generic formulations of cyclosporine, mycophenolate mofetil, and tacrolimus are AB rated by the FDA for bioequivalence, based on studies in normal volunteers as opposed to transplant patients. The narrow therapeutic window of these drugs warrants increased monitoring for efficacy and toxicity when switching formulations. While some clinicians may prefer to maintain patients on the innovator product to avoid additional monitoring, it may not be economically feasible for the patient. Patients should be advised to work with their pharmacist and inform the transplant center when they change product manufacturers.

GENERIC SUBSTITUTION

In recent years a number of generic versions of immunosuppressants have entered the market. While generic versions of corticosteroids and azathioprine have long been in the marketplace, there are now generic versions of cyclosporine, USP [MODIFIED], tacrolimus, and mycophenolate mofetil, the latter being considered narrow therapeutic index drugs. While these formulations have demonstrated bioequivalence to the innovator product in healthy individuals, bioequivalence testing in transplant patients is not required for approval.[77]

Although there would be no differences in the action of the molecule once absorbed into the systemic circulation, several potential differences in absorption could result in variability not seen in healthy volunteers. The presence of diabetes may delay gastric emptying, whereas cystic fibrosis may lead to differences in tacrolimus or cyclosporine secondary to fat malabsorption. None of these generic formulations have been studied in pediatric patients.[78,79]

As generic medications may offer a significant cost advantage compared with the innovator product, their use will increase over time. Much of the concern with generic substitution for immunosuppressant and other narrow therapeutic index medications relates to the potential for unmonitored changes in formulations. Systems that alert patients and prescribers to changes in formulation (e.g., labels on medications, direct notification to physicians) could trigger clinicians to more closely monitor patients for efficacy and toxicity as well as heightened therapeutic drug monitoring during a switch. However, the extent to which increased monitoring could offset cost savings associated with generic substitution has not been fully delineated.

IMMUNOSUPPRESSION-RELATED COMPLICATIONS

Comorbidities such as cardiovascular disease and malignancy, recurrent disease, drug toxicities (namely nephrotoxicity), and chronic rejection are the primary causes of mortality in patients who have a functioning graft 5 or more years after transplantation.[1]

CARDIOVASCULAR DISEASE

Cardiovascular disease is a leading cause of morbidity and mortality in transplant patients.[80] Preexisting cardiovascular disease, which is common in end-stage organ failure, is not reversed with transplantation. Additionally, hypertension, hyperlipidemia, and diabetes are common complications in transplantation recipients and are independent risk factors that contribute significantly to cardiovascular disease. Chronic rejection has been linked to hypertension and hyperlipidemia.[81,82]

HYPERTENSION

Corticosteroids, cyclosporine, tacrolimus, and impaired kidney graft function may cause post-transplantation hypertension. The primary mechanism of calcineurin inhibitor–associated hypertension in heart transplantation recipients may be related to the calcineurin inhibitor–induced stimulation of intact renal sympathetic nerves and the absence of reflex cardiac inhibition of the sympathetic nervous system, but a number of other mechanisms, including decreased prostacyclin and nitric oxide production have also been proposed.[39,83,84] In addition to the propensity to cause peripheral vasoconstriction, calcineurin inhibitors promote sodium retention, resulting in extracellular fluid volume expansion. Tacrolimus appears to have less potential to induce hypertension following transplantation than cyclosporine.[24,85]

Calcium channel blockers have traditionally been the first-line agents to treat hypertension after transplantation.[86] Calcium channel blockers may ameliorate the nephrotoxic effects of cyclosporine, improve renal hemodynamics, decrease the incidence of DGF and the development of allograft atherosclerosis, and provide some immunosuppression. Calcium channel blockers, however, may also contribute to gingival hyperplasia that is often associated with cyclosporine-based immunosuppression.[81]

ACEIs and angiotensin II receptor blockers have traditionally been avoided in kidney transplantation recipients, especially in the perioperative phase, because of the potential for hyperkalemia and their potentially negative influence on glomerular filtration rate. ACEIs and angiotensin II receptor blockers are now considered to be an equivalent alternative to calcium channel blockers for the treatment of hypertension in all transplant recipients. When ACEIs or angiotensin II receptor blockers are used in patients after transplantation, serum creatinine and potassium levels should be monitored closely. If the increase in serum creatinine is greater than 30% within 1 to 2 weeks after initiating ACEIs or angiotensin II receptor blockers, other alternatives must be considered (see Chap. 19).

Multiple antihypertensive agents are usually necessary to achieve the goal blood pressure in transplant recipients; consequently, the addition of a β-blocker, diuretic, or centrally acting antihypertensive is usually necessary. Beta-Blockers are generally considered to be second-line therapy in solid-organ transplantation recipients because of the potential to worsen metabolic disturbances caused by immunosuppressants, such as hyperkalemia and dyslipidemia. Calcineurin inhibitor–induced hypertension is often salt-sensitive, making it very responsive to diuretics. Central-acting agents (e.g., clonidine) are used often as adjunctive therapy in transplantation recipients who are unable to achieve blood pressure control with calcium channel blockers or ACEIs.

HYPERLIPIDEMIA

Hyperlipidemia may be exacerbated by corticosteroids, calcineurin inhibitors, sirolimus, diuretics, and β-blockers.[82,87] Corticosteroids promote insulin resistance and a decrease in lipoprotein lipase activity, as well as excessive triglyceride production. The mechanism of calcineurin inhibitor–induced hyperlipidemia is not well understood. Calcineurin inhibitors may decrease the activity of the low-density lipoprotein (LDL) receptor or lipoprotein lipase, altering LDL catabolism.[82] Tacrolimus appears to have less potential than cyclosporine to induce hyperlipidemia.[22,23,25,82] It is controversial whether the management of hyperlipidemia in transplant recipients should be more aggressive than current guidelines for the general population established by the National Cholesterol Education Program.[88] Aggressive lipid lowering may not only arrest the progress or prevent the complications of atherosclerosis but may also promote graft survival in the kidney and heart transplant recipients.

For most patients, the combination of dietary intervention and an HMG-CoA reductase inhibitor should be considered the treatment of choice. HMG-CoA reductase inhibitors are highly effective in the treatment of hyperlipidemia, especially increased LDL, in transplantation patients. HMG-CoA reductase inhibitors as a class also have immunomodulatory effects on MHC expression and T-cell activation and reduce cardiac allograft rejection.[82,89]

HMG-CoA reductase inhibitors should be used with caution in transplantation recipients because of several reports of rhabdomyolysis when these agents are combined with calcineurin inhibitors.[35,89] Safety measures include using low HMG-CoA reductase inhibitor doses and avoiding inappropriately high cyclosporine or tacrolimus concentrations. The concurrent use of medications known to increase the risk of myopathy (such as gemfibrozil) should be avoided.[82] Patients should be informed of the signs and symptoms of rhabdomyolysis. Baseline and follow-up creatine phosphokinase measurements (every 6 months) have been used to identify patients who develop subclinical rhabdomyolysis when cholesterol-lowering therapy is used. Pravastatin may be preferred as a result of its lower interactive potential with calcineurin inhibitors because it is not metabolized by CYP3A4. The potential for hepatotoxicity from HMG-CoA reductase inhibitors warrants close monitoring of liver function in all transplantation recipients.[87]

Bile acid–binding resins may be used to lower cholesterol in transplant patients, but adequate doses are difficult to achieve without the development of GI adverse effects. Because the absorption of cyclosporine is dependent on the presence of bile in the GI tract, patients should be instructed to separate dosing of bile acid–binding resins and cyclosporine by at least 2 hours. Bile acid–binding resins should also be separated from other immunosuppressants by at least 2 hours to avoid physical adsorption in the GI tract. For transplant patients who have hypertriglyceridemia refractory to dietary intervention, fish oil and fibric acid derivatives are well-tolerated, effective alternatives (see Chap. 28). Fibric acid derivatives are most effective in lowering serum triglyceride concentrations.

New-Onset Diabetes after Transplantation

Corticosteroids and calcineurin inhibitors can impair glucose control in previously diabetic patients, as well as cause new-onset diabetes after transplantation (NODAT) in 4% to 20% of patients. Corticosteroids induce insulin resistance and impair peripheral glucose uptake, whereas calcineurin inhibitors appear to inhibit insulin production.[82] Tacrolimus seems to be more diabetogenic than cyclosporine, although recent studies have failed to show a statistical difference.[22] Other possible risk factors that have been identified for NODAT include African American or Hispanic ethnicity, age >40 years, family history, and weight, as well as CMV and Hepatitis C virus infection.[82]

Up to 40% of patients with NODAT will require insulin therapy.[81] In diabetic patients who can be managed with an oral hypoglycemic agent, glipizide, which is metabolized extensively by the liver, may be preferred over renally eliminated agents such as glyburide. Metformin should be used with extreme caution because of the risk of accumulation and lactic acidosis in those with moderate renal impairment. Regardless of therapy, frequent blood glucose monitoring is imperative in the early postoperative phase both to improve glucose control and to identify those with NODAT. Changes in renal function secondary to calcineurin inhibitor nephrotoxicity or DGF or acute rejection in kidney transplant recipients affects the elimination of many hypoglycemic agents, including insulin, and may result in hyper- or hypoglycemia. Dose changes of immunosuppressant drugs also affect glycemic control. Tapering of immunosuppressive medications may result in reduced insulin requirements, whereas corticosteroid pulses for the treatment of rejection may result in increased insulin requirements.

INFECTION

Increased risk of infection is a natural consequence of therapeutic immunosuppression. Many infections, including cytomegalovirus and fungal infections, in solid organ transplant recipients are reviewed in Chapter 131.[90]

Polyomavirus-associated nephropathy (PVAN) is an important cause of renal dysfunction in kidney transplant recipients. The specific polyomavirus that infects kidney allografts is the BK virus. Primary infection with BK virus occurs in childhood as an asymptomatic infection in 50% to 90% of the general population. The precise mechanism of transmission is not clear but is suspected to be via the oral or respiratory routes. The virus then remains latent primarily in the genitourinary tract. Reactivation of BK virus is limited to people with compromised immune function and is most common in kidney transplant recipients. Reactivation can be detected as the presence of BK virus in the urine of approximately 30% to 40% of kidney transplant recipients, although it does not progress to nephropathy in the majority of patients. However, BK viremia if it develops has been noted to progress to allograft nephropathy in 50% of patients.[91] The development of BK virus nephropathy results in graft loss in about 46% of affected patients.[91]

It has been recommended that all kidney transplant recipients be screened for urinary BK virus replication at least every 3 months during the first 2 years post-transplant or in the event of any renal dysfunction or allograft biopsy. If positive, the result should be confirmed within 4 weeks by quantitative assay in plasma or urine. PVAN is definitively diagnosed by kidney allograft biopsy but may be mistaken for acute rejection if the pathologist does not recognize the presence of BK virus inclusions in renal tubular cells. Differentiation between the two is very important as treatment of acute rejection with increased immunosuppression can worsen BK virus nephropathy. The mainstay of treatment is a reduction in immunosuppression, which should be instituted when BK viremia is detected. The risks of acute rejection resulting from decreased immunosuppression must be weighed against the potential benefits of resolving BK viremia. Cidofovir, a potent nephrotoxic antiviral used for the treatment of CMV retinitis, has also been used for the treatment of BK virus in very low doses (0.25–0.33 mg/kg) without probenicid administered every 2 to 3 weeks.[92]

Hepatitis C recurs almost universally following liver transplantation, resulting in chronic hepatitis or cirrhosis in 90% of patients by 5 years. These patients tend to experience a much more aggressive course than that observed in immunocompetent patients. While short-term survival is not affected, hepatitis C virus infection recurrence results in the need for retransplantation in more than 10% of patients originally transplanted for hepatitis C virus. Pegylated interferons as monotherapy or in combination with ribavirin have been used after liver transplantation, in both the acute and chronic phases of hepatitis C virus infection and as prophylactic or preemptive therapy. Although some patients do achieve sustained viral responses, the rates are generally lower than for immunocompetent patients, 10% to 30% versus 30% to 70%, respectively, for combination therapy. Preexisting anemia and renal dysfunction make it difficult to maintain ribavirin at effective doses. Combination of immunosuppressive drugs and interferon may result in dose-limiting neutropenia. Administration of hematopoietic growth factors may be needed to allow administration of adequate doses of interferons and ribavirin. Even with these adjunctive therapies high rates of therapy discontinuation are still reported.[93,94]

In the absence of preventative therapy, hepatitis B recurs in approximately 80% of patients. Initial studies with short-term

intravenous administration of hepatitis B immunoglobulin (HBIg) showed equally high rates of recurrence upon discontinuation of therapy. However, strategies that employ the long-term administration of HBIg with or without antiviral therapy report much lower recurrence rates, 15% to 30% and 20% to 40%, for nonreplicative and replicative hepatitis B virus, respectively. Common strategies include intravenous HBIg 10,000 units during the anhepatic phase followed by 10,000 units daily for 6 days. Antihepatitis B surface titer should be monitored weekly to ensure adequate levels for protection as well as to optimize HBIg use. HBIg has been typically dosed to maintain titers >100 to 500 international units/L. Long-term HBIg therapy is extremely costly, estimated at $100,000 for the first postoperative year and $50,000 for each subsequent year. Combination therapy with antiviral agents appears to be synergistic and is the current standard. Lamivudine resistance is a concern with long-term utilization both pre- and post-transplant. The role of newer antiviral agents, including adefovir, entecavir, and tenofovir, remains to be defined. Other strategies that have been investigated and show promise include pretransplant viral load reduction and reduced-dose HBIg. Treatment for active hepatitis B virus graft infection should include HBIg, antiviral therapy, and concomitant reduction in immunosuppression.[94]

MALIGNANCY

Although advances in immunosuppression have decreased the incidence of acute rejection and increased patient survival, they have also increased the patient's lifetime exposure to immunosuppression. While the precise mechanism is unclear, post-transplantation malignancy seems to be related to the overall level of immunosuppression, as evidenced by a difference in the rates of malignancy associated with quadruple versus triple versus dual immunosuppressant regimens. The risk of de novo malignancy in transplantation recipients is increased three- to fivefold over the general population. The age-adjusted incidence of lung, breast, colon, and prostate cancers was doubled in renal transplant recipients. A number of cancers that are uncommon in the general population occur with much higher prevalence in transplantation recipients: post-transplantation lymphomas and lymphoproliferative disorders (PTLDs), Kaposi sarcoma, renal carcinoma, in situ carcinomas of the uterine cervix, hepatobiliary tumors, and anogenital carcinomas. Skin cancers are the most common tumors. Factors that may predispose transplant recipients to skin cancers include copious sun exposure and therapy with azathioprine.[95] While too early to definitively assess the impact of mycophenolic acid derivatives on malignancy, one analysis showed a lower risk of PTLD with MMF compared with AZA. Inhibitors of mTOR have a theoretical benefit in terms of the development of malignancy. In addition to immunosuppressive properties, mTOR inhibitors also have antiproliferative effects. In fact, a decreased incidence of malignancy was reported in patients receiving mTOR inhibitors versus CNIs, and conversion to PSIs from CNIs can result in regression of Kaposi sarcoma.[95]

PTLD encompasses a broad spectrum of disorders, ranging from benign polyclonal hyperplasias to malignant monoclonal lymphomas. Factors that predispose patients to PTLD include Epstein-Barr virus seronegativity at transplantation and intense immunosuppression, particularly with OKT3 and antithymocyte globulin. Nonrenal transplantation recipients are more likely to develop PTLD secondary to the heavy immunosuppression used to reverse rejection. Administration of ganciclovir or acyclovir preemptively during antilymphocyte therapy may decrease the risk of eventual PTLD. Treatment of life-threatening PTLD generally includes severe reduction or cessation of immunosuppression. Other options include systemic chemotherapy or rituximab.[96]

Post-transplantation malignancies appear an average of 5 years after transplantation and increase with the length of follow-up. As many as 72% of patients surviving greater than 20 years may be affected. Malignancy accounts for 11.8% of deaths after cardiac transplantation and is the single most common cause of death in the sixth to the tenth post-transplant years.[95]

CONCLUSIONS

Transplantation is a lifesaving therapy for several types of end-organ failure. Advances in the understanding of transplant immunology have produced an unprecedented number of choices in terms of immunosuppression. The increasing number of effective immunosuppressive medications and therapies offers clinicians diverse ways to prevent allograft rejection in a patient-specific manner. However, the vast array and efficacy of currently available immunosuppressive agents make it increasingly difficult to evaluate their long-term efficacy. Clinicians must be keenly aware of the adverse effects of immunosuppressive medications and their treatment in order to optimize the care of the transplanted patient.

ABBREVIATIONS

6-MP: 6-mercaptopurine
ACEI: angiotensin-converting enzyme inhibitor
ACR: acute cellular rejection
AMR: antibody-mediated rejection
ATG: antithymocyte globulin
ATN: acute tubular necrosis
AUC: area under the concentration curve
C_2: concentration 2 hours after dose
C_{max}: peak concentration
CMV: cytomegalovirus
CYP: cytochrome P450 liver enzyme system
DGF: delayed graft function
FKBP: FK-binding protein
GI: gastrointestinal
HBIg: hepatitis B immunoglobulin
HIV: human immunodeficiency virus
HLA: human leukocyte antigen
HPLC: high-performance liquid chromatography
IL: interleukin
LDL: low-density lipoprotein
MELD: model for end-stage liver disease
MHC: major histocompatibility complex
MPA: mycophenolic acid
MPAG: mycophenolic acid glucuronide
mTOR: mammalian target of rapamycin
NODAT: new-onset diabetes after transplantation
OKT3: muromonab-CD3
PML: progressive multifocal leukoencephalopathy
PRA: panel of reactive antibodies
PSI: proliferation signal inhibitor

PTLD: post-transplantation lymphoproliferative disorder

PVAN: polyomavirus associated nephropathy

RIA: radioimmunoassay

t_{max}: time to peak concentration

SECTION 12
RHEUMATOLOGIC DISORDERS

CHAPTER 99

Osteoporosis and Other Metabolic Bone Diseases

MARY BETH O'CONNELL AND SHERYL F. VONDRACEK

KEY CONCEPTS

1. Perimenopausal and postmenopausal women, men older than age 50 years, and those with potential disease- or medication-induced bone loss should be assessed for osteoporosis. Patients with early-onset or severe osteoporosis should be evaluated for secondary causes of bone loss.
2. Inadequate vitamin D concentrations, which sometimes cause osteomalacia, can be insidious and coexist with osteoporosis. A serum 25(OH) vitamin D concentration should be obtained in patients with osteoporosis, at high risk for low vitamin D concentrations, or with symptoms suggestive of inadequate vitamin D such as unexplained muscle weakness, falls, or pain.
3. Osteoporosis in men is often secondary to certain diseases and medications and responds well to a bone-healthy lifestyle, bisphosphonate or teriparatide therapy, and in some cases, testosterone replacement.
4. Estimation of an adult person's 10-year probability of developing an osteoporotic fracture can be estimated with the FRAX tool. Central bone densitometry can determine bone mass, predict fracture risk, and influence patient and provider treatment decisions. Portable equipment can be used for screening in the community to determine the need for further testing.
5. All people, regardless of age, should incorporate a bone-healthy lifestyle beginning at birth and continuing throughout life, that emphasizes regular exercise, nutritious diet, tobacco avoidance, minimal alcohol use, and fall prevention to prevent and treat osteoporosis.
6. The adequate intake for calcium in American adults is 1,000 to 1,200 mg of elemental calcium daily in divided doses from diet or supplements. The adequate intake for American adults is 400 to 1,000 units (seniors 800–1,000 units) of vitamin D daily, mainly from supplements, with some experts recommending higher doses.
7. Bisphosphonates decrease vertebral, hip, and nonvertebral fractures and are considered the medication of choice for osteoporosis treatment. Adherence with bisphosphonates is frequently suboptimal, which has been associated with less fracture prevention. Assessment of correct administration should be frequently conducted with repeat patient education as needed.
8. Raloxifene is an alternative treatment option to prevent vertebral fractures, particularly in women who cannot tolerate, should not, or will not take bisphosphonates. Raloxifene also decreases invasive breast cancer risk. Postmenopausal women at high risk for breast cancer might choose this medication to obtain dual benefits.
9. Healthcare providers can have an important role in prevention and treatment of osteoporosis by conducting osteoporosis assessments at health fairs and community pharmacies, identifying and resolving disease and medication-induced bone loss/osteoporosis, ensuring medications are taken accurately, identifying and resolving medication-related problems resulting in suboptimal adherence, and encouraging secondary fracture prevention in patients with past hip or vertebral fractures.
10. Patients taking long-term oral glucocorticoids need to be identified and started on a bone-healthy lifestyle with higher intakes of calcium and vitamin D and usually bisphosphonate therapy to prevent or treat osteoporosis.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Osteoporosis is a major public health threat for an estimated 44 million Americans or 55% of the people 50 years of age and older.[1] Low bone density (sometimes referred to as osteopenia) is estimated in 34 million Americans[1] and in 37% to 50% of white women.[2] In the United States, 8 million women and 2 million men are estimated to have osteoporosis. Osteoporosis is a bone disorder characterized by low bone density, impaired bone architecture, and compromised bone strength predisposing a person to increased fracture risk.[3] The development of osteoporosis and osteoporotic fractures is

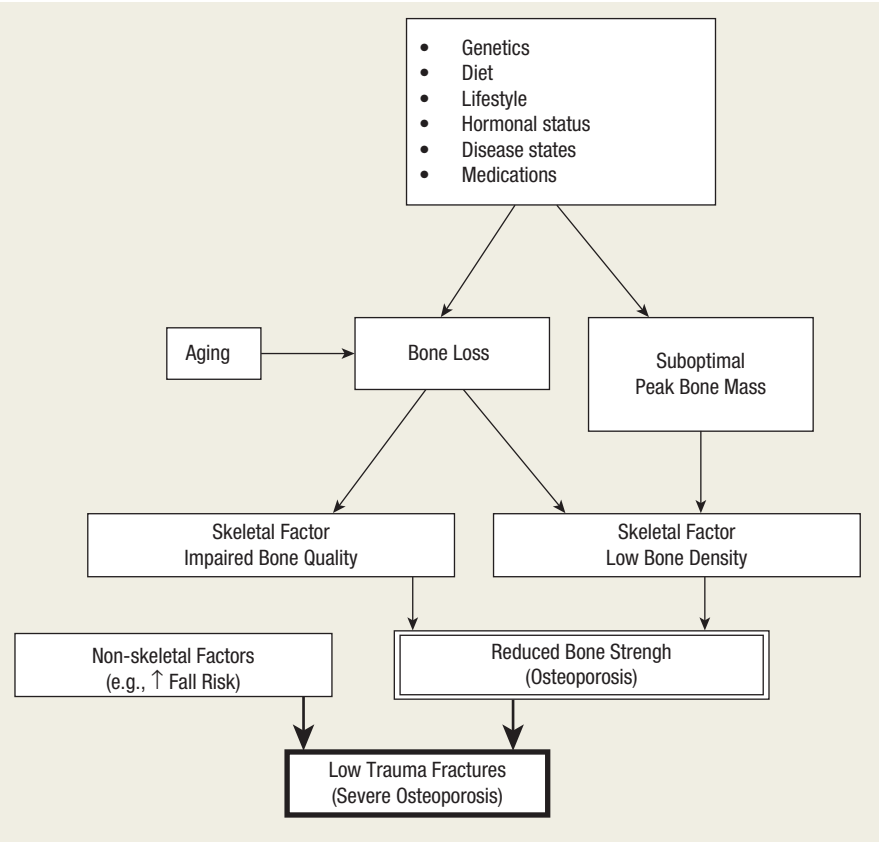

FIGURE 99-1. Etiology of osteoporosis and osteoporotic fractures.

multifactorial, beginning with genetics and lifestyles unhealthy for bone growth and maintenance, along with other skeletal factors, which lead to compromised bone strength, and nonskeletal factors that lead to falls (Fig. 99–1). Everyone must take an active role in educating people of all ages as well as other healthcare providers on healthy bone lifestyle habits and osteoporosis prevention and treatment options.

EPIDEMIOLOGY

1 Osteopenia, osteoporosis, and osteoporotic fractures are very common and affect all ethnic groups. Osteopenia is estimated to occur in 50% of Asian, 47% of Hispanic, 45% of Native American, 40% of white, and 28% of black women.[4] Osteoporosis affects 12% of Native American, 10% of Asian, 10% of Hispanic, 7% of white, and 4% of black women. Disease prevalence greatly increases with age; from 4% in women 50 to 59 years of age to 44% to 52% in women 80 years of age and older.[2] White and Hispanic women have the highest fragility fracture rate followed by Native American, African American, and Asian women when the data are adjusted for weight, bone mineral density (BMD), and other factors.[4] About 8 to 13 million men aged 50 years and older (i.e., 28%–47%) have osteopenia, with an osteoporosis prevalence of 6% to 13%.[5,6] Although osteoporosis is a common finding in seniors with fractures, up to 50% of fragility fractures occur in patients with normal bone mass or osteopenia.[2]

Low trauma (fragility) wrist and vertebral fractures are common throughout adulthood, and hip fractures are more common in seniors. Fracture incidence was estimated to be 2 million (71% in women, 29% in men) in 2005, with an estimated total medical cost of $17 billion.[7] Fractures in women accounted for 75% of the costs and in seniors 87% of the costs. Hip fractures represented 72% of these costs. Forecasting predicts 3 million fractures at a cost of $25 billion in 2025. Newer information is beginning to suggest that fracture incidence might be decreasing for both sexes,[8] with the hypothesis related to better efforts at osteoporosis prevention (e.g., improved risk factor identification, diagnosis, and bone-healthy lifestyle education) and use of prescription antiosteoporotic medications. In a woman's lifetime, she has a 17% likelihood of a hip fracture, 15.6% likelihood of a vertebral fracture, and 16% likelihood of a forearm fracture.[2] In a man's lifetime, osteoporotic fracture risk is 15%.[6]

BONE PHYSIOLOGY

The skeleton comprises two types of bone.[9] Cortical bone makes up the majority of the skeleton (80%) and is found mostly in the long bones (e.g., forearm and hip). Trabecular bone is found mostly in the vertebrae and ends of long bones. It is 10 times more metabolically active compared with cortical bone, having a much higher bone turnover rate because of its large surface area and honeycomb-like shape.

Bone is made of collagen and mineral components.[9] The collagen component gives bone its flexibility and energy-absorbing capability. The mineral component gives bone its stiffness and strength. The correct balance of these substances is needed for bone to adequately accommodate stress and strain and resist fractures. Imbalances can impair bone quality and lead to reduced bone strength.

Bone strength reflects the integration of bone quality and BMD (bone mass). Bone mass increases rapidly throughout childhood and adolescence. Ninety-five percent of peak bone mass is attained by age 18 to 20 years, with small gains until approximately age 30 years.[10] Peak bone mass is highly dependent on genetic factors that account for approximately 60% to 80% of the variability.[11] The remaining 20% to 40% is influenced by modifiable factors such as nutritional intake (e.g., calcium, vitamin D, and protein), exercise,

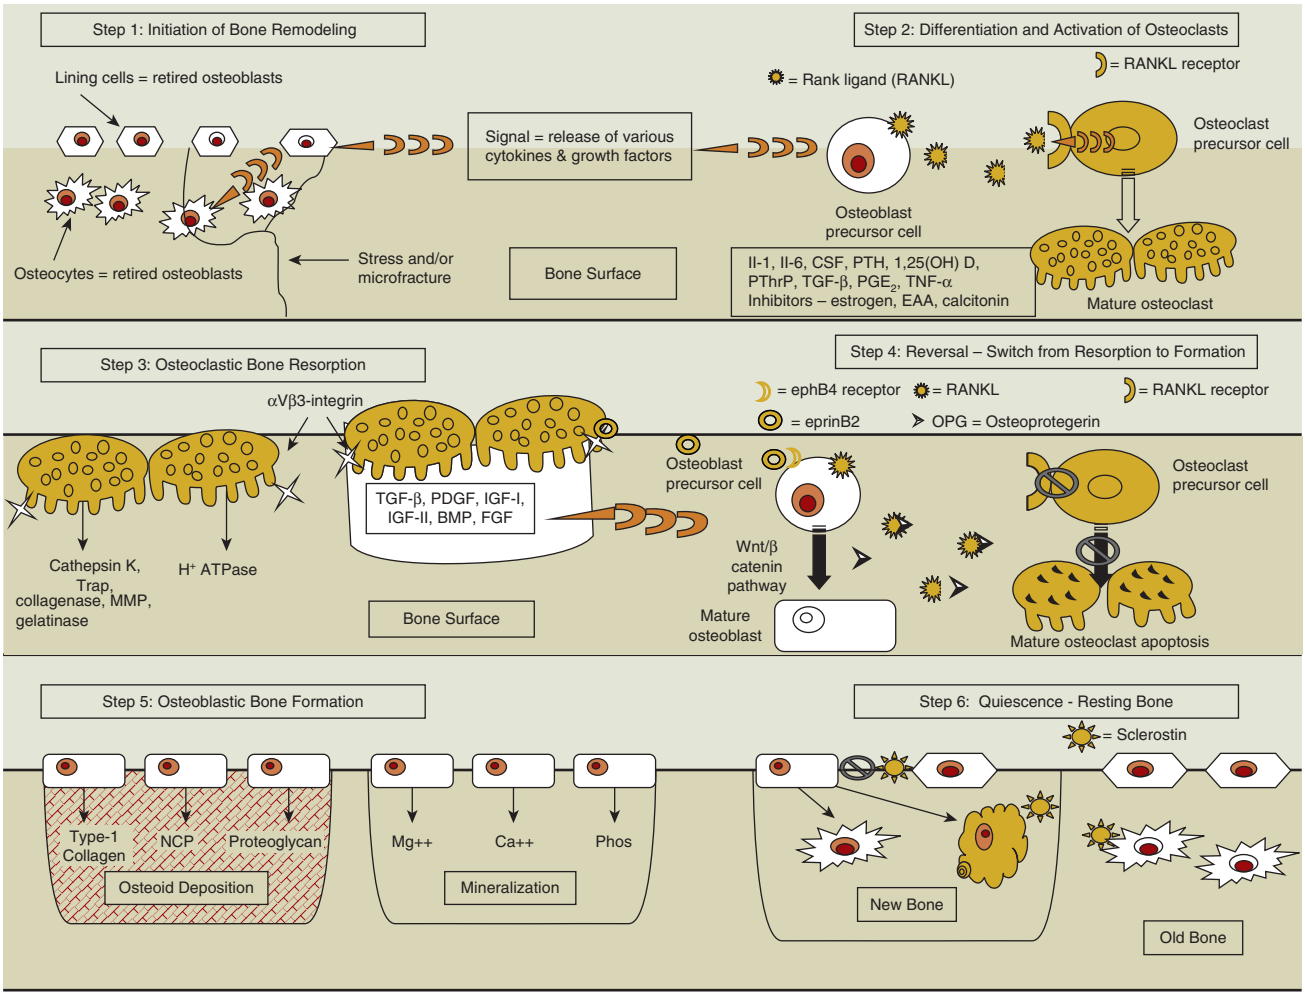

FIGURE 99-2. Bone remodeling cycle.[9,12–16] (1,25(OH) D, calcitriol/1α,25dihydroxyvitamin D; BMP, bone morphogenetic protein; Ca, calcium; CSF, colony-stimulating factors; EAA, estrogen agonist/antagonist; FGF, fibroblast growth factor; IGF, insulin-like growth factor; Il, interleukin; Mg, magnesium; MMP, matrix metalloproteinases; NCP, noncollagenous proteins; OPG, osteoprotegerin; PDGF, platelet-derived growth factor; PG, prostaglandin; Phos, phosphorous; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related protein; TGF, transforming growth factor; TNF, tumor necrosis factor; Trap, tartrate-resistant acid phosphate.)

adverse lifestyle practices (e.g., smoking), hormonal status, and certain diseases and medications. Optimizing peak bone mass is important for preventing osteoporosis. The higher the peak bone mass, the more bone one can lose before being at an increased fracture risk.

Bone remodeling is a dynamic process that occurs continuously throughout life Figure 99–2.[9,12–16] One to two million tiny sections of bone are in the process of remodeling at any given time. The complete physiology of bone remodeling is not fully known but appears to begin with signals from lining cells or osteocytes (bone communication cells) that are triggered by stress, microfractures, biofeedback systems, and potentially certain diseases and medications (see Fig. 99–2, step 1).[17] Many cytokines, growth factors, and hormones influence each remodeling step. A major stimulus for hematopoietic stem cell (monocyte–macrophage lineage) differentiation to become mature osteoclasts (bone resorbing cells) is the receptor activator of nuclear factor kappa B ligand (RANKL), which is emitted from the osteoblast (bone-forming cells) in step 2 and binds to its receptor RANK on the surface of osteoclast precursors. RANKL also stimulates mature osteoclast activation and bone adherence via integrins to resorb bone. Proteinases are secreted to resorb the protein matrix, and hydrogen ions are secreted to dissolve the mineralized component (step 3). After bone is resorbed and a cavity is created, additional cytokines and growth factors, some working through Wnt/β-catenin pathways, are released that first mature osteoblasts from mesenchymal stem cells and then stimulate bone formation (step 4). Osteoclasts also produce ephrinB2 that adheres to ephB4 receptors on osteoblasts and osteoblast precursors to stimulate osteoblast differentiation and activity. Mature osteoblasts produce osteoprotegerin (OPG) that binds (step 4) to RANKL, thereby stopping bone resorption.

Bone formation occurs over two phases.[9,13,16] First, osteoblasts fill the resorption cavity with osteoid, and then mineralization occurs (step 5). Once bone formation is complete, mature osteoblasts undergo apoptosis or become lining cells or osteocytes (step 6). Osteocytes produce sclerostin, which inhibits Wnt signaling and bone formation. Quiescence is the phase when bone is at rest until another remodeling cycle is initiated at that site.

With the mapping of the genome, exploration into genetic control of bone physiology and pathophysiology is being explored.[18] Nine genes have been mapped to BMD regulation and four genes to fracture risk. Genetic modulation is in its infancy for osteoporosis prevention and treatment but might lead to new medications.

Estrogen has many positive effects on the bone remodeling process, with most of its actions helping to maintain a normal bone resorption rate.[12,19] Estrogen suppresses the proliferation and differentiation of osteoclasts and increases osteoclast apoptosis. Estrogen decreases the production of several cytokines that are

potent stimulators of osteoclasts, including interleukins 1 and 6, and tumor necrosis factor-α. Estrogen also decreases the production of RANKL and increases the production of OPG, both of which reduce osteoclastogenesis.[20]

VITAMIN D, PARATHYROID HORMONE, AND CALCIUM

Vitamin D and parathyroid hormone (PTH) work together to maintain calcium homeostasis. The most abundant source of vitamin D is the endogenous production from exposure to ultraviolet B light. The sun's ultraviolet B light converts 7-dehydrocholesterol in the skin to cholecalciferol (vitamin D_3).[21,22] Dietary vitamin D sources include cholecalciferol and ergocalciferol (vitamin D_2). Subsequent conversion of cholecalciferol and ergocalciferol to 25-hydroxyvitamin D [25(OH) D] (calcidiol) occurs in the liver, and then PTH stimulates conversion of 25(OH) vitamin D via 25(OH) vitamin D-1α-hydroxylase to its final active form, 1α,25-dihydroxyvitamin D (calcitriol), in the kidney. Calcitriol binds to the intestinal vitamin D receptor and then increases calcium-binding protein. As a result, calcium and phosphorous intestinal absorption is increased.

Vitamin D receptors are also found in many tissues, such as bone, intestine, brain, breast, colon, heart, stomach, pancreas, lymphocytes, skin, and gonads.[22] Some cells within these tissues contain 1α-hydroxylase and have the capacity to convert vitamin D to its active form.[21] Vitamin D is increasingly recognized as contributing many nonbone benefits, and those may relate to the presence of these conversion capabilities and receptors throughout the body.

2 Inadequate concentrations of vitamin D are common in all age groups, especially in seniors and individuals who are malnourished or obese, live in an institution (e.g., nursing home), or live in more northern latitudes.[22] Low vitamin D concentrations result from insufficient intake, dietary fat malabsorption, decreased sun exposure, decreased skin production, or decreased liver and renal metabolism. Endogenous synthesis of vitamin D can be decreased by factors that affect exposure to or decrease skin penetration of ultraviolet B light. Sunscreen use, full body coverage with clothing (e.g., women wearing veiled, full-length dresses), and darkly pigmented skin can all cause a decrease in vitamin D production. Seasonal variations in vitamin D concentrations are also seen with nadirs in late winter and peaks in late summer.[22]

Calcium absorption under normal conditions is approximately 30% to 40%, decreasing to 10% to 15% with low vitamin D concentrations.[23,24] Calcium absorption is predominantly an active rate-limited process controlled by many hormones such as vitamin D and estrogen. Less than 15% is absorbed through passive diffusion, which is not rate limited.[25,26] A calcium transporter is required to bring calcium from the gut into the tissue wall. There it binds to calbindin to be transported across the enterocyte and is extruded into the circulation via Ca^{2+} adenosinetriphosphatase (ATPase) and the sodium/calcium exchanger (NCX). When the calcium sensing receptor (CaSR) on parathyroid cells senses low serum calcium, PTH production increases. PTH then increases calcitriol production and calcium reabsorption by the kidney. Calcium absorption increases as 25(OH) vitamin D concentrations increase until 29 to 32 ng/mL (72–80 nmol/L) when the effect plateaus; this observation provides the rationale for the cutoff point for vitamin D sufficiency at around 30 ng/mL (75 nmol/L).[22,27] Sometimes the increased fractional calcium absorption is insufficient to maintain normal serum calcium, and thus bone resorption is needed for correction. Together, PTH and calcitriol increase osteoclast activity, thereby releasing calcium from bone to restore calcium homeostasis.

TABLE 99-1 Risk Factors for Osteoporosis and Osteoporotic Fractures[2,3,28]

Low bone mineral density[a]
Female sex[a]
Advanced age[a]
Race/ethnicity[a]
History of a previous low-trauma (fragility) fracture as an adult[a]
Osteoporotic fracture in a first-degree relative (especially parental hip fracture[a])
Low body weight or body mass index[a]
Premature menopause (before 45 years old)[b]
Secondary osteoporosis[b] (especially rheumatoid arthritis[a])
Past or present systemic oral glucocorticoid therapy[a]
Current cigarette smoking[a]
Alcohol intake of three or more drinks per day[a]
Low calcium intake
Low physical activity
Minimal sun exposure
Poor health/frailty
Recent falls
Cognitive impairment
Impaired vision

[a]Factors included in the World Health Organization fracture risk assessment tool (FRAX).
[b]Secondary causes included in the FRAX tool question are diabetes type 1, osteogenesis imperfecta as an adult, long-standing untreated hyperthyroidism, hypogonadism, premature menopause (before 45 years of age), chronic malnutrition, malabsorption, and chronic liver disease.

ETIOLOGY

1 Figure 99–1 depicts a model describing the etiology of osteoporosis and fractures. Table 99–1[2,3,28] lists risk factors for osteoporosis, and Tables 99–2[2,5,29,30] and 99–3[31,32] list secondary causes of this condition.

LOW BONE DENSITY

BMD is a major predictor of fracture risk. Every standard deviation decrease in BMD in women represents a 10% to 12% decrease in bone mass and a 1.5- to 2.6-fold increase in fracture risk.[2] Low BMD can occur as a result of bone loss or failure to reach a normal peak bone mass.

Bone loss occurs when bone resorption exceeds bone formation, usually from high bone turnover; when the number or depth of bone resorption sites greatly exceeds the rate and ability of osteoblasts to form new bone. Women and men begin to lose a small amount of bone mass starting in the third to fourth decade of life as a consequence of a slight reduction in bone formation.[33] During perimenopause and for up to 4 years after menopause, women can experience an accelerated rate of bone loss because of the drop in circulating estrogen and subsequent increase in bone resorption.[2,20] The rate and duration of loss can vary greatly, with up to 2% to 5% of bone density lost per year, and can differ depending on the skeletal site measured. Seniors steadily lose bone mass at approximately 0.5% to 1.5% per year as a consequence of an accelerated rate of bone remodeling combined with reduced bone formation.[2,16]

The major factors (see Tables 99–1, 99–2, and 99–3) influencing bone losses are hormonal status, exercise, aging, nutrition, lifestyle, disease states, medications, and some genetic influences. Nonhormonal risk factors are similar between women and men.

IMPAIRED BONE QUALITY

In addition to BMD, the strength of bone is highly affected by the quality of the bone's material properties and its structure.[33] For example, accelerated bone turnover can result in bone loss but can also impair bone quality and the structural integrity of bone by

TABLE 99-2 Select Medical Conditions Associated with Osteoporosis in Children and Adults[2,5,29,30]

Endocrine/hormonal
Primary or secondary ovarian failure
Testosterone deficiency
Hyperthyroidism
Cushing's disease

Hemochromatosis
Hyphophosphatasia

increasing the quantity of immature bone that is not yet adequately mineralized. Also, bone loss resulting in thinning of trabeculae—as seen in men with aging—is less damaging to the quality of bone structure compared with bone loss that results in damage to trabecular crosslinks, which results in decreased bone strength/quality, as seen in women.[34] Bone quality assessment is important because changes in bone quality affect bone strength much more than bone mass changes. Future osteoporosis diagnostic testing will assess both bone quality and density.

FALLS

Although up to 50% of vertebral fractures can occur spontaneously with minimal to no trauma, most wrist fractures and greater than 90% of hip fractures result from a fall from standing height or less.[2] One third to one half of all seniors fall each year, and 50% fall more than once. Up to 5% of all falls will result in a fracture. According to 2006 statistics, 2.1 million seniors were treated in the emergency department and 600,000 hospitalized for fall-related injuries, incurring costs of about $20 billion.[35] Close to 17,000 seniors died in 2006 due to a fall-related injury.[36]

PATHOPHYSIOLOGY

Osteoporosis pathophysiology depends on sex, age, genetics,[18] and presence of secondary causes.

POSTMENOPAUSAL OSTEOPOROSIS

The accelerated bone loss during perimenopause and postmenopause results from enhanced resorption, mainly as a result of the loss in ovarian hormone production, specifically estrogen. Estrogen deficiency increases proliferation, differentiation, and activation of new osteoclasts and prolongs survival of mature osteoclasts.[12,19] Interleukins, prostaglandin E_2, tumor necrosis factor α, and interferon γ also increase, resulting in more RANKL and less OPG. Loss of estrogen also increases calcium excretion and decreases

Medications	Comments
AIDS/HIV medications	
Nucleoside reverse transcriptase inhibitors (antiretroviral therapy, ART) (zidovudine, didanosine, lamivudine)	↓ BMD (ART > PI), no fracture data; increased osteoclast activity and decreased osteoblast activity
Protease inhibitors (PI) (nelfinavir, indinivir, saquinavir, ritonavir, lopinavir)	
Anticonvulsant therapy (phenytoin, carbamazepine, phenobarbital, valproic acid)	↓ BMD and ↑ fracture risk; increased vitamin D metabolism leading to low 25(OH) vitamin D concentrations
Aromatase inhibitors (e.g., letrozole, anastrozole)	↓ BMD and ↑ fracture risk; reduced estrogen concentrations
Furosemide	↑ fracture risk; increased calcium renal elimination
Glucocorticoids (long-term oral therapy)	↓ BMD and ↑ fracture risk; dose and duration dependent; see special populations section
Gonadotropin-releasing hormone (GnRH) agonists or analogs (e.g., leuprolide, goserelin)	↓ BMD and ↑ fracture risk; decreased sex hormone production
Heparin (unfractionated, UFH) or low molecular weight heparin (LMWH)	↓ BMD and ↑ fracture risk (UFH >>> LMWH) with long-term use (e.g., >6 mo); decreased osteoblast function and increased osteoclast function
Medroxyprogesterone acetate depot administration (DMPA)	↓ BMD, no fracture data; possible BMD recovery with discontinuation; central DXA monitoring of BMD recommended with ≥2 years of use; decreased estrogen concentrations
Proton pump inhibitor therapy (long-term therapy)	↑ vertebral and hip fracture risk; possible calcium malabsorption secondary to acid suppression for carbonate salts
Selective serotonin reuptake inhibitors	↑ hip fracture risk; decreased osteoblast activity
Thiazolidinediones (TZDs) (pioglitazone, rosiglitazone)	↓ BMD and ↑ fracture risk; risk may be greater in women than men; decreased osteoblast function
Thyroid–excessive supplementation	↓ BMD and ↑ fracture risk (> in men); risk increases with TSH concentration <0.1 μIU/mL (<0.1 mIU/L); possible increase in bone resorption
Vitamin A–excessive intake (≥1.5 mg of retinol form)	↓ BMD and ↑ fracture risk; decreased osteoblast activity and increased osteoclast activity

BMD, bone mineral density; TSH, thyroid-stimulating hormone; DXA, dual-energy x-ray absorptiometry.

calcium gut absorption. The number of remodeling sites increases, and resorption pits are deeper and inadequately filled by normal osteoblastic function. Significant bone density is lost and bone architecture is compromised. Trabecular bone is most susceptible, leading to vertebral and wrist fractures.

MALE OSTEOPOROSIS

3 Bone physiology of men is under both estrogen and androgen control and influenced by similar hormones and cytokines as female bone.[12] Men are at a lower risk for developing osteoporosis and osteoporotic fractures because of larger bone size, greater peak bone mass, increase in bone width with aging, and fewer falls.[34,37] Men also do not undergo a period of accelerated bone resorption similar to menopause. However, men have a higher mortality rate after fractures.

The etiology of male osteoporosis tends to be multifactorial with secondary causes (see Tables 99–2 and 99–3) and aging being the most common contributing factors.[6,37] In young and middle-age men, a secondary cause for bone loss is usually identified, with hypogonadism being the most common. Idiopathic osteoporosis (no known cause) can occur.

AGE-RELATED OSTEOPOROSIS

Age-related osteoporosis occurs in seniors, mainly as a result of hormone, calcium, and vitamin D deficiencies leading to an accelerated bone turnover rate in combination with reduced osteoblast bone formation.[16] Hip fracture risk rises dramatically in seniors as a consequence of the cumulative loss of cortical and trabecular bone and an increased risk for falls.

SECONDARY CAUSES OF OSTEOPOROSIS

1 A secondary cause (see Tables 99–2 and 99–3) is identified in more than half of premenopausal and perimenopausal women, about one third of postmenopausal women, and more than two thirds of men.[2,6,29–31] The most common secondary cause for osteoporosis is glucocorticoid therapy, which is discussed later in the Glucocorticoid-Induced Osteoporosis section.

CLINICAL PRESENTATION

Table 99–4 outlines the clinical presentation of osteoporosis.

Osteoporosis is diagnosed by BMD measurement or presence of a fragility (i.e., low trauma) fracture. Two thirds of patients with a vertebral fracture are asymptomatic or attribute mild lower back pain to "old age." The other third present with moderate to severe back pain that radiates down their leg after a new vertebral fracture. The pain usually subsides significantly after 2 to 4 weeks; however, residual chronic lower back pain may persist. Multiple vertebral fractures decrease height and sometimes curve the spine (kyphosis or lordosis) with or without significant back pain. Patients who have experienced a nonvertebral fracture frequently present with severe pain, swelling, and reduced function and mobility at the fracture site.

CONSEQUENCES OF OSTEOPOROSIS

A fragility fracture is defined as one that occurs as a result of a fall from standing height or less or with minimal to no trauma. Fractures of the vertebrae, hip, forearm, or humerus are considered major osteoporotic fractures.[28] Fractures of the face, skull, fingers, and toes are typically not considered osteoporosis-related. Osteoporotic fractures can lead to increased morbidity and mortality and decreased quality of life. Depression is common because of fear, pain, loss of self-esteem from physical deformity, and loss of independence and mobility.

Symptomatic vertebral fractures can cause significant pain, physical deformity, and adverse health consequences. Patients with severe kyphosis can experience respiratory problems as a result of compression of the thoracic region and gastrointestinal complications, such as poor nutrition, from intraabdominal compression. Women and men who suffer a symptomatic vertebral fracture have a lower survival rate compared with those without a fracture history.[3]

Wrist fractures occur more commonly in younger postmenopausal women and are frequently a result of a fall on an outstretched hand. Negative outcomes include prolonged pain and weakness, and decreased advanced (instrumental) activities of daily living (such as cooking and shopping).

Hip fractures are associated with the greatest increase in morbidity and mortality. In 2006, hip fractures resulted in approximately 330,000 hospital admissions.[38] Nearly 90% of these were in seniors. After a hip fracture, only 50% of patients regain their ability to perform basic activities of daily living, while 20% become nonambulatory.[39,40] Overall, 3% to 54% of patients die during the initial hospitalization for hip fracture, and 14% to 36% die within 1 year either from complications of the hip fracture or other comorbid disease processes. Men have a twofold higher 1-year mortality rate after hip fracture than women.

Once a low-trauma fracture has occurred, the risk for subsequent fractures goes up exponentially. In subjects with one clinical vertebral fracture, the chance of experiencing any new fracture was 2.8-fold higher, and with two or more vertebral fractures it was 12-fold higher, than for subjects who did not have baseline fractures.[41]

TABLE 99-4 Clinical Presentation of Osteoporosis

General
- Many patients are unaware they have osteoporosis and present only after fracture
- Fractures can occur after bending, lifting, or falling, or independently of any activity

Symptoms
- Pain
- Immobility
- Depression, fear, and low self-esteem from physical limitations and deformities
- Two thirds of vertebral fractures are asymptomatic

Signs
- Shortened stature (loss of more than 1.5 inches [3.8 cm]), kyphosis, or lordosis
- Vertebral, hip, wrist, or forearm fracture
- Low bone density on radiography

Laboratory tests
- Routine tests to detect a possible secondary cause: complete blood count, creatinine, calcium, phosphorous, alkaline phosphatase, albumin, and thyroid-stimulating hormone. Free testosterone, 25(OH) vitamin D, and 24-hour urine concentrations of calcium and phosphorous are frequently assessed
- Urine or serum biomarkers (e.g., NTX, osteocalcin) are sometimes used, especially to determine if high bone turnover exists
- Additional testing might be necessary if the patient's history, physical examination, or the initial laboratory or diagnostic tests suggest a specific secondary cause

Other diagnostic tests
- Spine and hip bone density measurement using dual-energy x-ray absorptiometry (DXA)
- Vertebral fracture assessment (VFA) with DXA technology
- Radiograph (routine lateral thoracolumbar x-ray) to confirm vertebral fracture

NTX, N-terminal crosslinking telopeptide of type 1 collagen.

PATIENT ASSESSMENT

Bone pain, postural changes (i.e., kyphosis), and loss of height are simple useful physical examination findings. A height loss greater than 1.5 inches (3.8 cm) from the tallest mature height is considered significant and warrants further investigation. Height should be routinely measured using a wall-mounted stadiometer. Proper technique is essential, as can be seen at the National Institutes of Health Web site.[42] A spine radiograph can be obtained to confirm the presence of vertebral fractures. Low bone density or osteopenia reported on routine radiographs is a sign of significant bone loss and requires further evaluation for osteoporosis. In addition to physical examination and laboratory studies (see Table 99–4), patients can be assessed with risk factor assessments, osteoporosis questionnaires, peripheral and central dual-energy x-ray absorptiometry (DXA), and biomarkers.[5]

RISK FACTOR ASSESSMENT

4 The aim of an initial osteoporosis risk assessment (see Table 99–1) is to identify those patients who are at highest risk for low bone density and who would benefit from further evaluation. Many risk factors for osteoporosis have been identified and are similar for both sexes. The majority of risk factors are predictors of either low BMD (e.g., female sex, ethnicity) or an increased fracture/fall risk (e.g., cognitive impairment, previous falls). The most important risk factors are those associated with fracture risk independent of BMD and fall risk. These major risk factors, in combination with BMD, are used to determine which patients are at greatest risk for fracturing and would benefit most from pharmacologic intervention.

A fracture prediction model used for treatment risk stratification was developed by the World Health Organization (WHO).[5,28,43] The WHO model for the United States uses the following risk factors: age, race/ethnicity, sex, previous fragility fracture, parent history of hip fracture, body mass index, glucocorticoid use (ever), current smoking, alcohol use of three or more drinks per day, rheumatoid arthritis, and select secondary causes with femoral neck BMD data optional to predict an individual's percent probability of fracturing in the next 10 years. Other osteoporosis risk assessment tools exist but are usually just used in research versus patient care.[5]

SCREENING USING PERIPHERAL BONE MINERAL DENSITY DEVICES

Peripheral bone density devices that utilize x-ray absorptiometry or quantitative ultrasonometry are helpful as screening tools to determine which patients require further evaluation with central DXA.[44] They should not be used for diagnosis or for monitoring response to therapy. Peripheral DXA of the forearm, heel, and finger uses a low amount of radiation. Heel quantitative ultrasonometry uses sound waves without radiation or need for specialty training.

Because peripheral devices are considerably less expensive than central DXA, easy to use, portable, fast (<5 minutes), and can predict general fracture risk, they are very popular for screening patients at health fairs, community pharmacies, and clinics. No guidelines specifically address who should undergo peripheral bone density screening.[45] However, the best population to screen is younger postmenopausal women without major risk factors for osteoporosis because a low peripheral BMD value in this population would support the need for further testing. The specific peripheral T-score threshold for referral is not universally defined and varies by device.[46] Healthy premenopausal women and patients already identified as being at high risk for osteoporosis based on risk factors, fragility fracture, or secondary causes for osteoporosis, should not be screened but rather referred to a physician for central DXA testing.

CENTRAL DUAL-ENERGY X-RAY ABSORPTIOMETRY

4 BMD measurements at the hip or spine can be used to assess fracture risk, establish the diagnosis and severity of osteoporosis, and sometimes confirm osteoporosis as causative for low-trauma fractures.[2,5,44] Central DXA is considered the gold standard for measuring BMD because of its high precision, short scan times, low radiation dose (comparable to the average daily dose from natural background), and stable calibration. Measurement of lumbar spine, proximal femur, and total hip BMD is recommended with the lowest BMD value used for diagnosis. Newer methods, such as micromagnetic resonance imaging, are undergoing investigation to provide measurements of bone quality in addition to bone density.[44]

Several consensus guidelines or position statements are available that discuss which patients should undergo central DXA testing.[2,3,5,46] Most are consistent in recommending central BMD testing for all women aged 65 years or older, men aged 70 years or older, postmenopausal women younger than 65 years of age and men 50 to 69 years old with risk factors for fracture, and patients with an identified secondary cause for bone loss. Patients with a fragility fracture do not need a DXA for an osteoporosis diagnosis, but the results are helpful for determining the severity of osteoporosis and as a baseline for monitoring response to therapy. The DXA results can also help patients make decisions about the need for lifestyle changes and prescription osteoporosis medications. In the absence of a suspected or known secondary cause for osteoporosis or a history of a low-trauma fracture, central BMD testing is not recommended for children, premenopausal women, or men under 50 years of age.

A central DXA BMD report provides the actual bone density value, T-score, and Z-score. The actual bone density value (g/cm^2) is most useful for serial monitoring of therapy response, which is typically performed 1 to 2 years after medication initiation. The T-score is used for diagnosis and is a comparison of the patient's measured BMD to the mean BMD of a healthy, young (20- to 29-year-old), sex-matched white reference population. The T-score is the number of standard deviations from the mean of the reference population. Ethnic-specific reference databases are not recommended at this time. The Z-score is similar but compares the patient's BMD to the mean BMD for a healthy sex- and age-matched population. Patient-reported ethnicity should be used for the Z-score if available. The Z-score is sometimes helpful in determining whether a secondary cause for osteoporosis is present and is used for diagnosis in children, premenopausal women, and men younger than 50 years of age.

Using the spine DXA image, an assessment of morphometric vertebral fractures, the vertebral fracture assessment (VFA), can be calculated.[47] Initially a research tool, this analysis of T4 to L4 vertebrae after a DXA is increasing in utilization, especially for seniors. Each vertebra is assessed for compression (wedge, biconcave, and crush) and described as normal or mild, moderate, and severe compression. This result becomes important for treatment decisions in patients with low bone mass

LABORATORY TESTS

Laboratory testing (see Table 99–4) is used to identify secondary causes of bone loss. If a preliminary investigation indicates a possible secondary cause, additional testing might be needed.

2 Serum 25(OH) vitamin D is the best indicator of total body vitamin D status. Data suggest that serum 25(OH) vitamin D

concentrations of at least 75 nmol/L or 30 ng/mL (1 ng/mL = 2.5 nmol/L) are necessary to maximize intestinal calcium absorption, minimize secondary hyperparathyroidism, and reduce fracture risk.[21,22] Although still highly debated, most experts believe that the goal 25(OH) vitamin D concentration should be 30 to 100 ng/mL (75–250 nmol/L); concentrations between 20 and 29 ng/mL (50–72 nmol/L) are insufficient for optimal health, and concentrations below 20 ng/mL (50 nmol/L) would constitute deficiency.[48,49] Osteomalacia or severe vitamin D deficiency, which is discussed later under the Other Metabolic Bone Disorders section, can occur at concentrations less than 10 ng/mL (25 nmol/L).[50]

Because vitamin D assays are fairly expensive and large interlab assay variability exists, routine vitamin D screening cannot be recommended at this time. However, a 25(OH) vitamin D concentration should be considered in anyone at higher risk for low vitamin D (e.g., seniors, patients who are obese or who have minimal sun exposure, insufficient vitamin D intake, dark pigmented skin, or certain medical conditions, or are on medications known to affect vitamin D metabolism), and patients with low bone density, history of a low-trauma fracture or frequent falls, or history of unexplained muscle weakness and/or bone pain.

BONE TURNOVER MARKERS

Urine and serum bone turnover markers are either enzymes or proteins produced during bone formation or breakdown.[51,52] Bone-specific alkaline phosphatase, osteocalcin, and procollagen type 1 propeptides are examples of bone formation markers. Hydroxypyridinium crosslinks of collagen pyridinoline and deoxypyridinoline, C-terminal crosslinking telopeptide of type 1 collagen, and N-terminal crosslinking telopeptide of type 1 collagen are examples of bone resorption markers. Increased concentrations of bone resorption markers (≥2 standard deviations above the premenopausal range) have been shown in some studies to predict fracture risk; however, results have been inconsistent. Although not diagnostic, these tests might be helpful in identifying accelerated bone turnover and increased fracture risk or in monitoring response to therapy.

DIAGNOSIS OF OSTEOPOROSIS

The diagnosis of osteoporosis is based on a low-trauma fracture or central hip and/or spine DXA using WHO T-score thresholds. Osteopenia or low bone mass is a T-score between −1 and −2.5, and osteoporosis is a T-score at or below −2.5.[2,3,5,46] Although these definitions are based on data from postmenopausal white women, they are applied to perimenopausal women, men age 50 years and older, and other race/ethnic groups. The diagnosis of osteoporosis in children, premenopausal women, and men under 50 years of age should be based on a Z-score at or below −2.0 in combination with other risk factors or fracture.[46]

PREVENTION AND TREATMENT

Osteoporosis

The foundation for osteoporosis prevention and treatment is a bone healthy lifestyle beginning at birth and continuing throughout life. Supplements and medications are used when lifestyle habits are suboptimal and/or osteoporosis has developed.

DESIRED OUTCOMES

The primary goal of osteoporosis management should be prevention. Optimizing skeletal development and peak bone mass accrual in childhood, adolescence, and early adulthood will ultimately reduce the future incidence of osteoporosis. Once low bone mass or osteoporosis develops, the objective is to stabilize or improve bone mass and strength and prevent fractures. In patients who have already suffered osteoporotic fractures, reducing pain and deformity, improving functional capacity, improving quality of life, and reducing future falls and fractures are the main goals.

GENERAL APPROACH TO PREVENTION AND TREATMENT

5 A bone-healthy lifestyle should begin at birth and continue throughout life. Insuring adequate intakes of calcium and vitamin D along with other bone-healthy lifestyle practices are the first steps in prevention and treatment. Recent guidelines/position statements recommend considering prescription therapy in any postmenopausal woman or man age 50 years and older presenting with one of the following scenarios: a hip or vertebral fracture; T-score of −2.5 or lower; or low bone mass (T-score between −1.0 and −2.5) with a secondary cause associated with a high risk for fracture, a history of prior fracture, a 10-year probability of hip fracture of 3% or more, or a 10-year probability of any major osteoporosis-related fracture of 20% or more.[2,3] Figure 99–3 provides an osteoporosis management algorithm for postmenopausal women and men 50 years and older that incorporates both nonpharmacologic and pharmacologic approaches.

NONPHARMACOLOGIC THERAPY

4 Nonpharmacologic therapy, referred to as a bone-healthy lifestyle, includes a nutritious diet, smoking cessation, minimal alcohol intake, exercise, and fall prevention. Consumers might opt for self-care and use the Internet for decisions about osteoporosis management, especially regarding options that are natural or available without a prescription. Since Internet information can be wrong or misleading,[53] consumers should discuss nonprescription medication choices with a healthcare professional.

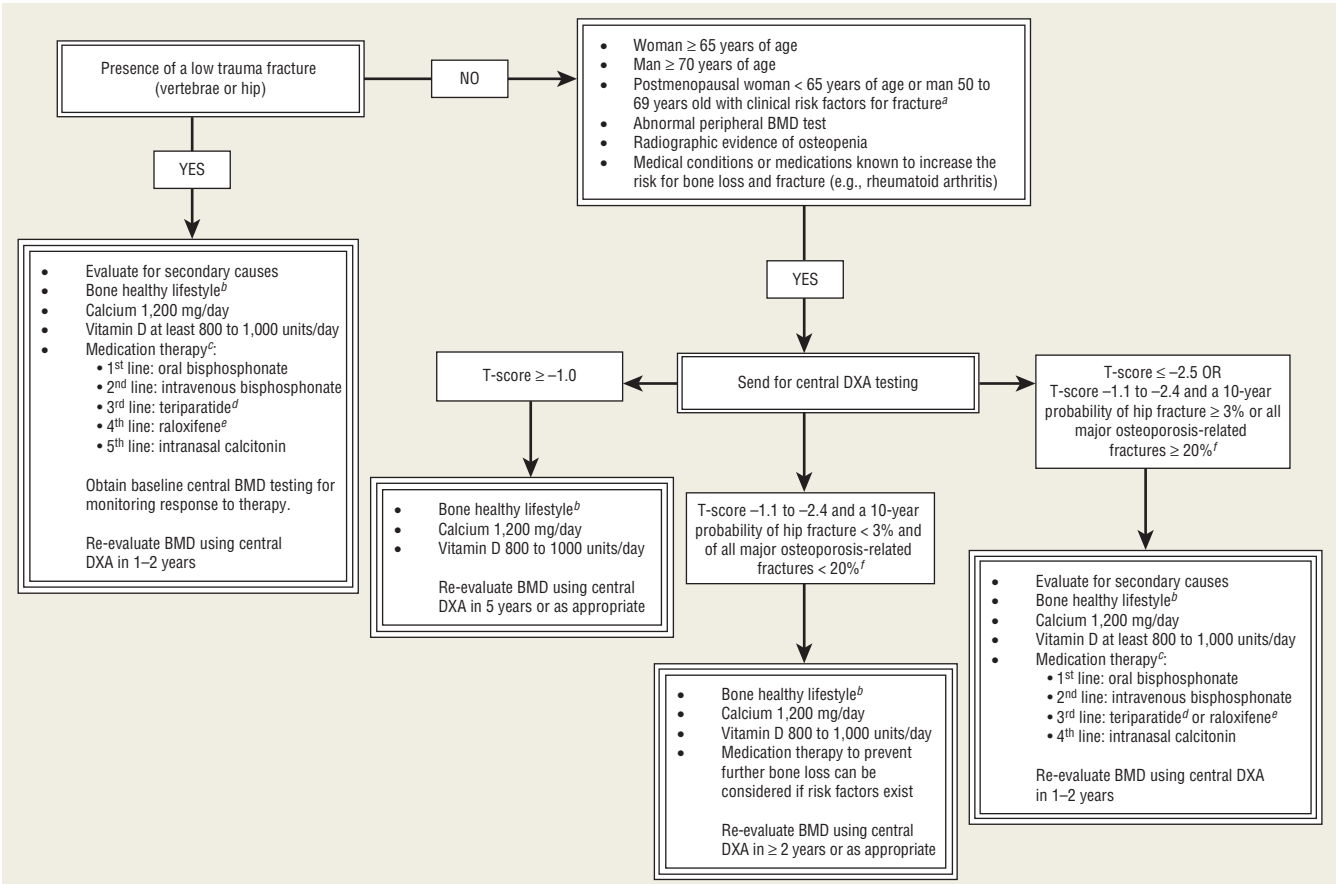
Diet

Overall, a diet well balanced in nutrients and minerals and limited in alcohol, caffeine, and carbonated cola beverages[54] is important for bone health.

Calcium 5 6 Data clearly indicate that adequate calcium intake is necessary for the development of bone mass during growth and for its maintenance throughout life.[2,55] Adequate calcium intake is an essential component of all osteoporosis prevention and treatment strategies.

Table 99–5 summarizes the recommended intakes for calcium based on age.[56–59] Achieving daily calcium requirements from calcium-containing foods,[57,60] which also contain other essential nutrients, is preferred. Milk and other dairy products have the highest amount of calcium per serving and are available in low-fat options. Some food sources are absorbed well but have low elemental calcium content (e.g., broccoli). Other foods contain oxalic acid (e.g., spinach) or phytic acid (e.g., wheat bran) that bind calcium contained in the food, decreasing its absorption.[57] For example, to get the same amount of calcium in one 8-ounce (~240 mL) glass of milk, one would need to eat 2.25 cups (~530 mL) of cooked broccoli or 8 cups (~1900 mL) of cooked spinach.

People should be encouraged to evaluate their food and beverage intake to determine if they are receiving adequate intakes.



[a]Major clinical risk factors for fracture: current smoker, low body weight or body mass index, history of osteoporosis/ low trauma fracture in a first-degree relative, personal history of fracture as an adult (after age 50 years), excessive alcohol intake
[b]Bone-healthy lifestyle includes smoking cessation, limit alcohol intake, well-balanced diet with adequate calcium and vitamin D intakes, weight-bearing/resistance exercises, and fall prevention
[c]Men with hypogonadism might also receive testosterone replacement; women with menopausal symptoms might receive low dose hormone therapy for a short time
[d]Teriparatide can be considered a 1st line option in patients with a T-score < –3.5 or if multiple low trauma fractures
[e]Raloxifene might be a good option in women at high risk for breast cancer
[f]WHO absolute fracture risk assessment tool (FRAX) for osteoporotic fracture risk estimations
(BMD, bone mineral density; DXA, dual-energy x-ray absorptiometry)

FIGURE 99-3. Algorithm for the management of osteoporosis in postmenopausal women and men aged 50 and older.[2,3]

To calculate the amount of calcium in a serving of food, consumers can add a zero to the percentage of the daily value listed on food labels. For example, a serving of milk (8 oz. [~240 mL]) has 30% of the daily value of calcium. This translates to 300 mg calcium per serving.

Approximately 25% of the U.S. population has some level of lactose intolerance, with the incidence in Asian (80%) and African American (50%) populations being much higher than in whites (10%).[57] Lactose-intolerant patients have several options, including products containing lactase (Lactaid), lactose-reduced milk, lactose-free milk, calcium-fortified soy milk, certain aged cheeses, or yogurt with active cultures along with other nondairy calcium-fortified products (e.g., orange juice, breakfast cereals, and energy bars).

TABLE 99-5 Calcium and Vitamin D Recommended Daily Intakes[56–59]

Group and Ages	Elemental Calcium (mg)[a,b]	Vitamin D (units)[b]
Infants		
Birth to 6 months	210	400[c]
6–12 months	270	400[c]
Children/Adolescents		
1–3 years	500	400[c]
4–8 years	800	400[c]
9–18 years	1,300	400[c]
Adults		
19–49 years	1,000	400 – 800[d]
≥50 years	1,200	800 – 1,000[d]

[a]Recommendations from the U.S. Institute of Medicine of the National Academy of Sciences. Most experts feel the vitamin D dose for 19–49 years old is too low. New Institute of Medicine recommendations were due in 2010 after this chapter was prepared.
[b]U.S. Institute of Medicine of the National Academies recommends not to exceed more than 2,500 mg/day elemental calcium or 2,000 units/day of vitamin D (controversial).[56]
[c]2008 recommendations from the American Academy of Pediatrics.[58]
[d]2008 recommendations from the National Osteoporosis Foundation.[59]

Vitamin D 5 6 Table 99–5 lists the recommended adequate intakes for Vitamin D.[3,56,58] The three main sources of vitamin D are sunlight, diet, and supplements. Websites can be used to identify the few foods high in vitamin D.[61] To calculate the amount of vitamin D in a serving of food, multiply the % daily value of vitamin D listed on the food label by 4 (e.g., 20% vitamin D = 80 units). Because few foods are naturally high or fortified with vitamin D, most people, especially seniors, require supplementation.

Other Nutrients and Minerals Vitamin K is a cofactor for carboxylation (activation) of proteins, such as osteocalcin, which are involved in bone formation. Several studies have demonstrated that vitamin K deficiency can contribute to bone loss and an increased risk for fractures.[62,63] Studies evaluating the benefits of vitamin K supplementation are conflicting, with some demonstrating reduced

bone loss and fracture risk. More data are needed before recommending routine supplementation. Some calcium supplements already contain vitamin K. This is important to note for patients receiving warfarin therapy.

Minimal to no data exist for other nutrients and minerals such as potassium, boron, and magnesium.[55,64] Until more data are available, taking a multivitamin once daily and consuming a healthy diet, following the U.S. Department of Agriculture food pyramid recommendations for daily fruit and vegetable intake, should provide an adequate intake of these vitamins and minerals for general bone health.

Dietary Soy Isoflavone phytoestrogens are plant-derived compounds that possess weak estrogenic agonist and antagonist effects. The most common source for isoflavone is dietary soy products. Genistein is the most abundant and biologically active isoflavone in soybeans. The evidence supporting a positive bone benefit from soy protein (isoflavone) intake is conflicting, with some studies showing improvements in bone density with larger isoflavone intakes.[2,65] Only one study has evaluated the association between soy intake and fracture risk. This population-based prospective cohort study from China demonstrated that higher isoflavone intake was associated with a significantly lower risk of fractures. Since isoflavones from soy foods appear safe, patients can be encouraged to increase their intake, but true benefits on fracture are not clear. More information is needed on the safety of isoflavone supplements, especially in women with breast cancer.

Alcohol 5 Alcohol consumption in moderation is not associated with an increased risk for osteoporosis or fractures. Excessive alcohol intake increases osteoporosis risk because of poor nutrition, impaired calcium and vitamin D metabolism, and an increased risk for falls.[2] According to 2005 dietary guidelines, alcohol consumption should not exceed one drink per day for women and two drinks per day for men.[66]

Caffeine 5 Although results are conflicting, excessive caffeine consumption is associated with increased calcium excretion, increased rates of bone loss, and a modestly increased risk for fracture.[67] Ideally, caffeine consumption should be limited to two servings or less per day. Moderate caffeine intake (two to four servings per day) should not be a concern if adequate calcium intake is achieved daily.

Carbonated Beverages 5 Consumption of cola beverages, even without caffeine, is associated with decreased BMD and increased fracture risk; however, data are conflicting.[54] The phosphoric acid content of cola beverages is thought to contribute to bone loss by altering calcium balance. This effect is compounded by decreased milk consumption and consequent reductions in calcium intake with the increase in carbonated beverage intake seen in the United States.[55]

Smoking Cessation

5 Counseling patients of all ages on smoking cessation can help to optimize peak bone mass, minimize bone loss, and ultimately reduce fracture risk. Cigarette smoking is an independent risk factor for osteoporosis and is associated with up to an 80% increased relative risk for hip fracture.[2,68] The effect is dose and duration dependent. A decrease in sex hormone concentrations, reduced intestinal calcium absorption, a direct toxic effect on osteoblasts, and detrimental effects of smoking on neurovascular function have been implicated for the negative bone effects.

Exercise

5 Physical activity or exercise is an important nonpharmacologic approach to preventing osteoporotic fractures. Exercise can decrease the risk of falls and fractures by stabilizing bone density and improving muscle strength, coordination, balance, and mobility.[2] Physical activity is especially important early in life as lack of exercise during growth can lead to suboptimal loading/straining, decreased stimulation of bone deposition, and a subsequently reduced peak bone mass. All patients who are medically fit should be encouraged to perform a moderate-intensity weight-bearing activity (e.g., walking, jogging, golf, stair climbing) for at least 30 minutes most days of the week and a resistance activity (e.g., weight machines, free weights, or elastic bands) at least twice per week for 20 to 30 minutes.[3]

Fall Prevention

5 Risk of falling increases with advanced age predominantly as a result of balance, gait, and mobility problems, poor vision, reduced muscle strength, impaired cognition, multiple medical conditions (e.g., stroke, Alzheimer's dementia, Parkinson disease), and polypharmacy.[2,69] Psychoactive medications such as benzodiazepines, antidepressants, antipsychotics, sedative–hypnotics, and opioids have been strongly associated with falls.

The ability to adapt to falls also decreases with aging. Seniors are more likely to sustain a hip or pelvic fracture because they tend to fall backward or sideways instead of forward.

Because of the link between falls and fractures, patients who experience an acute fall, have more than two falls per year, or have walking or balance problems should have a falls assessment and potentially a multidisciplinary intervention program (e.g., falls clinic).[69] Intervention programs are documented to decrease falls, fractures, other injuries, and nursing home and hospital admissions.[70]

Patients should be educated on personal and home safety options to decrease falls.[2,69] Websites provide great patient education materials with solutions for commonly observed safety problems.[71–73] Medication profiles should also be reviewed for any unnecessary medications that can affect cognition and balance and potentially increase fall risk. Consideration should be given to replacing high-risk medications with safer alternatives. Adequate vitamin D intake has been associated with reduced falls.[74,75] Maintenance of a regular individualized exercise program, such as tai chi, should be recommended to improve body strength, balance, and agility.

Other recommendations include resolving vision, blood pressure, heart rate/rhythm, and foot problems and using proper footwear.

External hip protectors are specialized undergarments designed to pad the area surrounding the hip, decreasing the force of impact from a sideways fall. Conflicting results and poor adherence limit their use.[2]

PHARMACOLOGIC THERAPY

Because nonpharmacologic interventions alone are frequently insufficient to prevent or treat osteoporosis, medication therapy is often necessary. Table 99–6[2,3,5,76] describes fracture and BMD effects, and Table 99–7 describes important aspects of common osteoporosis medications. These medications should always be combined with a bone-healthy lifestyle.

MEDICATION

Treatments of First Choice

Combined with adequate calcium and vitamin D intakes, bisphosphonates are the prescription medication of choice, with teriparatide, denosumab, raloxifene, and calcitonin considered alternative agents.[2,3] Duration of bisphosphonate therapy has not been defined, but safety data exist for periods of 7 to 10 years. Short-term (18–24 months) teriparatide is usually reserved for

Drug	Adult Dosage	Pharmacokinetics	Adverse Effects	Drug Interactions
Antiresorption Medications				
Calcium	200–1,300 mg/day to achieve adequate intake (see Table 99–5); divided doses	Absorption–predominantly active transport with some passive diffusion; fractional absorption 10%–60%; calcium carbonate absorption improved if given with food; fecal elimination for the unabsorbed and renal elimination for the absorbed calcium	Constipation, gas, upset stomach, rare kidney stones; potential concern about doses >1,500 mg daily	• Carbonate products – decreased absorption with proton pump inhibitors • Decrease absorption of iron, tetracycline, quinolones, alendronate, risedronate, etidronate, phenytoin, and fluoride when given concomitantly • Antagonist of verapamil • Induce hypercalcemia with thiazide diuretics • Fiber laxatives, oxalates, phytates, and sulfates can decrease calcium absorption if given concomitantly
Vitamin D D_3 (cholecalciferol)	400–1,000 units/day to achieve adequate intake (see Table 99–5); if low 25(OH) vitamin D concentrations, malabsorption or multiple anticonvulsants might require higher doses (>2,000 units daily)	Hepatic metabolism to 25 (OH) vitamin D and then renal metabolism to 1,25 (OH) vitamin D, the active moiety for bone effects; other active and inactive metabolites	Hypercalcemia, (weakness, headache, somnolence, nausea, cardiac rhythm disturbance), hypercalciuria	• Phenytoin, barbiturates, carbamazepine, rifampin increase vitamin D metabolism • Cholestyramine, colestipol, orlistat, or mineral oil decrease vitamin D absorption • May induce hypercalcemia with thiazide diuretics in hypoparathyroid patients
D_2 (ergocalciferol)	For vitamin D deficiency, 50,000 units once to twice weekly for 8–12 weeks; repeat as needed until therapeutic concentrations; occasionally 50,000 units monthly for maintenance			
1,25(OH) vitamin D (calcitriol, Rocaltrol po, Calcijex iv)	0.25–0.5 mcg orally or 1–2 mcg/mL intravenously daily for renal osteodystrophy, hypoparathyroidism, or refractory rickets			
Bisphosphonates Alendronate (generic, Fosamax)	5 mg daily, 35 mg weekly (prevention) 10 mg daily or 70 mg tablet, 70 mg tablet with vitamin D 2,800 or 5,600 units, or 75 mL liquid weekly (treatment)	Poorly absorbed (<1%), decreasing to zero with food or beverage intake; long bone $t_{1/2}$ (2–10 years); renal elimination (of absorbed) and fecal elimination (unabsorbed)	Common: nausea/dyspepsia (oral); transient flu-like illness (injectables) Rare: GI perforation, ulceration, and/or bleeding (oral); musculoskeletal pain; osteonecrosis of the jaw; atypical fractures	• Do not coadminister with any other medication or supplements (including calcium and vitamin D)
Risedronate (Actonel)	5 mg daily, 35 mg weekly, 75 mg for 2 days monthly, 150 mg monthly			
Ibandronate (Boniva)	150 mg monthly, 3 mg intravenous quarterly			

(continued)

TABLE 99-7 Medications Used to Prevent and Treat Osteoporosis (continued)

Drug	Adult Dosage	Pharmacokinetics	Adverse Effects	Drug Interactions
Antiresorption Medications				
Zoledronic acid (Reclast)	5 mg intravenous infusion yearly (treatment), 5 mg intravenous infusion every 2 year (prevention)			
Estrogen Agonist/Antagonist Raloxifene (Evista)	60 mg daily	Hepatic metabolism	Hot flushes, leg cramps, venous thromboembolism, peripheral edema, rare cataracts, and gallbladder disease; black-box warning for fatal stroke	None
Bazedoxifene[a] (Viviant, Conbriza)	20 or 40 mg daily			
Bazedoxifene with conjugated equine estrogens[a] (Aprela)	20 or 40 mg daily plus 0.45 or 0.625 mg daily			
Lasofoxifene (Fablyn)[a]	0.25–0.5 mg daily			
Calcitonin (Miacalcin)	200 units intranasally daily, alternating nares every other day	Renal elimination 3% nasal availability	Rhinitis, epistaxis	None
Denosumab (Prolia)	60 mcg subcutaneously every 6 months	T_{max} = 10 days, $t_{1/2}$ = 25.4 days	Back, extremity, and musculoskeletal pain; hypercholesterolemia, cystitis, serious infection, skin problems, osteonecrosis of the jaw, and bone turnover suppression	None
Formation Medications				
Teriparatide (PTH 1–34 units) (Forteo)	20 mcg subcutaneously daily for up to 2 years	95% bioavailability T_{max} ~30 minutes $t_{1/2}$ ~60 minutes Hepatic metabolism	Pain at injection site, nausea, headache, dizziness, leg cramps, rare increase in uric acid, slightly increased calcium	None

T_{max}, time to maximum concentration; $t_{1/2}$, half-life; GI, gastrointestinal; im, intramuscular
[a]Investigational product

severe osteoporosis and then followed by bisphosphonate therapy. The algorithm (see Fig. 99–3) helps determine for whom medication therapy should be used. Osteoporosis prescription medications in children, pre- and perimenopausal women, and men younger than 50 years old are controversial and undergoing further investigation.

Published Guidelines and Treatment Protocols

The 2008 National Osteoporosis Foundation's clinician's guide and the 2010 North American Menopause Society's position statement provide guidance on osteoporosis prevention and treatment strategies.[2,3] Some additional subspecialty guidelines exist (e.g., osteoporosis and gastrointestinal [GI] diseases[77]) but will not be covered here. Applying the National Osteoporosis Foundation's guidelines to a large clinical database, researchers found that about 72% of women ≥65 years old and 93% of women ≥75 years old would be eligible for treatment.[78] Even with guidelines and algorithms, many patients are not being evaluated nor receiving appropriate osteoporosis therapy, even after a hip fracture.[5]

Antiresorptive Therapies

Antiresorptive therapies include calcium, vitamin D, bisphosphonates, estrogen agonists antagonists (known previously as selective estrogen receptor modulators or SERMs), calcitonin, denosumab, estrogen, and testosterone.

Calcium Supplementation 5 6 Calcium imbalance can result from inadequate dietary intake, decreased fractional calcium absorption, or enhanced calcium excretion. Adequate calcium intake (see Table 99–5) is considered the standard for osteoporosis prevention and treatment and should be combined with vitamin D and osteoporosis medications when needed.[56,57] Supplemental calcium intake will be needed in the majority of people with or at risk for osteoporosis as survey data indicate that the average U.S. female and male diet contains only 660 and 797 mg calcium per day, respectively.[2,57]

Efficacy. Although calcium increases BMD, fracture prevention is minimal. Almost all trials and observational studies showed the children and adults with the higher calcium intakes had greater increases or maintenance of BMD compared to BMD losses with placebo.[55] Calcium's BMD effects are less than other antiresorptive and formation osteoporosis medications. Fracture prevention is only documented with concomitant vitamin D therapy. Some data support other calcium benefits such as decreased blood pressure, cholesterol, and colorectal cancer risk.[79]

Adverse Events/Precautions. Calcium's most common adverse reaction, constipation, can first be treated with increased water intake, dietary fiber, and exercise. If still unresolved, smaller and

more frequent administration or lower total daily dose can be tried. Calcium carbonate can create gas and cause stomach upset, which might resolve with calcium citrate, a product with fewer GI side effects. While the upper tolerable limit for calcium is 2,500 mg/day, consistently exceeding daily recommended intakes does not provide additional benefits and might increase certain patients' risk for heart disease.[80] Therefore, average daily calcium dietary intake needs to be known to calculate correct safe supplementatal dose.

Calcium rarely causes kidney stones. Some patients with a history of kidney stones can still ingest adequate amounts of calcium depending on the type of stones and/or will require increased fluid intake and decreased salt intake with their calcium supplementation.

Administration. Most children and adults of all ethnic backgrounds do not ingest sufficient dietary calcium and therefore require supplements. To ensure adequate calcium absorption, 25(OH) vitamin D concentrations should be maintained in the normal range (30 – 100 ng/mL [75 – 250 nmol/L]).[22] Because fractional calcium absorption is dose limited, maximum single doses of 500 to 600 mg or less of elemental calcium are recommended. Calcium carbonate is the salt of choice as it contains the highest amount of elemental calcium (40%) and is the least expensive. Calcium carbonate should be taken with meals to enhance absorption. Calcium citrate absorption (21% calcium) is acid-independent and need not be administered with meals. Although tricalcium phosphate contains 38% calcium, calcium-phosphate complexes could limit overall calcium absorption. This product might be helpful in patients with hypophosphatemia that cannot be resolved with increased dietary intake. Disintegration and dissolution rates vary significantly between products and lots. Products labeled "USP Verified" for "United States Pharmacopeia," which guarantees the identity, strength, purity, and quality of the product, should be recommended when possible. Oyster shell (other than the OsCal brand) or coral calcium should not be recommended because of concerns for high concentrations of lead and other heavy metals. Some calcium products come in alternative dosage forms (e.g., chews, dissolvable tablet, liquid), which can be beneficial for select patients (e.g., swallowing problems).

"Bone designer" nonprescription products continue to be developed by combining calcium and vitamin D with other nutrients, some of which are associated with bone physiology (e.g., magnesium, manganese, boron, vitamin K).[55,64] Newer products contain genistein, phytosterols, and aspirin. Minimal BMD and no fracture data exist for these combination products. Because product labeling is confusing, patients might not realize they need four to six tablets per day to obtain adequate calcium intakes. These products are also more expensive. Combining too many vitamins and supplements might lead to upper-tolerable nutrient limits being exceeded and a concern for toxicities.

Vitamin D Supplementation 5 6 Vitamin D intake is critical for the prevention and treatment of osteoporosis because it maximizes intestinal calcium absorption. Given its safety, low cost, and other benefits of vitamin D, no patient should have an inadequate intake.

Efficacy. Data show that higher dose vitamin D supplementation is needed for fracture and fall prevention. Based on a meta-analysis, higher doses of vitamin D (>400 units daily) decreased nonvertebral and hip fractures by approximately 20%.[81] These results are consist with a previous meta-analysis showing doses of 700 to 800 units reduced fractures, but doses of 400 units per day did not.[82] Some but not all studies support vitamin D decreasing falls.[74,75] Conflicting results between studies are thought to be a result of differences in vitamin D dosing, concomitant calcium administration, adherence, and baseline vitamin D status of subjects.

Vitamin D has other potential nonskeletal benefits. Improvement in muscle strength and cardiovascular function, decreased cancer risk (e.g., breast, colon, and prostate cancers), and positive immunomodulatory effects (e.g., multiple sclerosis, type 1 diabetes, rheumatoid arthritis) have been proposed.[21]

Administration. Seniors and patients being treated for osteoporosis should take at minimum 800 to 1,000 units of vitamin D through food and supplementation with a goal to maintain their 25(OH) vitamin D concentration within the sufficient range (i.e., ≥30 ng/mL [≥ 75 nmol/L]).[2,3] Several experts believe higher doses (i.e., up to 4,000 units of vitamin D daily) should be recommended, especially in certain populations.[27] In one Canadian study, 1,000 units vitamin D daily only resulted in 35% of seniors in the therapeutic range (> 30 ng/mL [>75 nmol/L]), whereas 4,000 units per day resulted in 88% in the therapeutic range.[83] In another study, 3,800 units were required to achieve and maintain therapeutic ranges when patients' initial 25(OH) vitamin D concentration was at least 22 ng/mL [55 nmol/L]); 5,000 units were required for those with a 25(OH) vitamin D concentration less than 22 ng/mL (55 nmol/L].[84]

Whether cholecalciferol (vitamin D_3) is more efficient than ergocalciferol (vitamin D_2) at raising 25(OH) vitamin D concentrations is controversial, with data supporting both arguments.[22,85] Usual supplementation is with daily nonprescription cholecalciferol vitamin D products. However, higher-dose prescription ergocalciferol regimens administered weekly, monthly, or quarterly are used for replacement and maintenance therapy.[22] Approximately 100 units vitamin D_3 daily will raise the 25(OH) vitamin D concentration by 1 ng/mL (2.5 nmol/L). More than one multivitamin or large doses of cod liver oil daily are no longer advocated because of the risk of hypervitaminosis A, which can increase bone loss. Because the half-life of vitamin D is about 1 month, approximately 3 months of therapy are required before a new steady state is achieved and a repeat 25(OH) vitamin D concentration can be obtained.

Individuals with deficient concentrations of vitamin D are at risk for osteomalacia. Their management is discussed in Other Metabolic Bone Diseases later in the chapter. In patients with disorders affecting vitamin D absorption (e.g., celiac disease, cystic fibrosis, or Crohn's disease), higher doses and more frequent monitoring are required. In patients with severe hepatic or renal disease, the activated form of vitamin D (calcitriol) might be more appropriate. However, new information with regard to vitamin D's nonbone effects suggests replacement with both cholecalciferol and calcitriol might be needed.[21]

CLINICAL CONTROVERSY

Some experts believe that the upper tolerable limit for vitamin D should be raised and that the recommended daily allowance for vitamin D should be at least 2,000 units per day. In one study, up to 4,000 units vitamin D daily was needed for approximately 90% of the sample to maintain 25(OH) vitamin D concentrations at ≥30 ng/mL (≥75 nmol/L).[83,84] Some suggest daily doses less than 10,000 units would be safe.[21] The dietary reference intakes are currently being reevaluated by the Institute of Medicine of the National Academy of Sciences.

Bisphosphonates 7 Bisphosphonates mimic pyrophosphate, an endogenous bone resorption inhibitor.[86] Bisphosphonate antiresorptive activity results from blocking prenylation and inhibiting guanosine triphosphatase-signaling proteins, which lead to decreased osteoclast maturation, number, recruitment, bone adhesion, and life span. Their various R2 side chains produce different bone binding, persistence, and affinities; however, the

resulting clinical significances are not known. All bisphosphonates become incorporated into bone, giving them long biologic half-lives of up to 10 years. Alendronate, risedronate, and intravenous zoledronic acid are FDA-indicated for postmenopausal, male, and glucocorticoid-induced osteoporosis (see Table 99–7). Intravenous and oral ibandronate are indicated only for postmenopausal osteoporosis.

Efficacy. Of the antiresorptive agents, bisphosphonates consistently provide some of the higher fracture risk reductions and BMD increases (see Table 99–6).[2,3,5,76,87] Fracture clinical trial data only exist for daily oral bisphosphonate and annual intravenous therapy, not weekly, monthly, or quarterly regimens. Although hip fracture reduction was not seen with daily oral ibandronate, the hip fracture incidence in the placebo group was low, suggesting the study might have been underpowered. Fracture reductions are demonstrated as early as 6 months, with the greatest fracture reduction seen in patients with lower initial BMD and in those with the greatest BMD changes with therapy. Although comparative fracture prevention trials do not exist, no differences between oral bisphosphonates and fractures were found based on claims data.[88] Annual intravenous zoledronic acid has documented both secondary fracture prevention and a decrease in mortality in the treated group.[89] Zoledronic acid has also been documented to decrease bone loss and fractures for patients receiving certain chemotherapy.[90]

BMD increases with bisphosphonates are dose dependent and greatest in the first 6 to 12 months of therapy. Small increases continue over time at the lumbar spine, but plateau after 2 to 5 years at the hip. After discontinuation, the increased BMD is sustained for a prolonged period of time that varies depending on the bisphosphonate used.[91] Weekly alendronate, weekly and monthly risedronate, and monthly oral and quarterly intravenous ibandronate therapy produce equivalent BMD changes to their respective daily regimens. Weekly alendronate therapy increases BMD more than weekly risedronate therapy[92]; however, no evidence indicates that this difference would equate to greater fracture efficacy. Weekly alendronate and monthly ibandronate produced similar BMD effects.[93]

The BMD increases with alendronate, risedronate, and zoledronic acid in men are similar to those in postmenopausal women.[37] Because of a lack of fracture data from pivotal trials in men, bisphosphonates are only FDA indicated to increase BMD, not to reduce fracture risk in men. Pooled analysis of risedronate studies did document fracture prevention in men, and alendronate has been shown to decrease radiographic but not clinical vertebral fractures.[94,95]

CLINICAL CONTROVERSY

Women without evidence of a low-trauma fracture and who have responded well to bisphosphonate therapy—for example, those with BMD increasing into the osteopenic range (e.g., T-score > −2)—are being considered for a "drug holiday."[91] Patients are taken off their bisphosphonate therapy and followed serially with bone turnover markers and central DXA BMD. The FLEX study demonstrated prolonged suppression of bone turnover and maintenance of BMD in selected postmenopausal women after 5 years off of alendronate therapy. Data with risedronate after 1 year of discontinuation indicated a continued fracture benefit despite significant increases in bone turnover markers and decreases in BMD.[2,91] No data about effects after discontinuation with the other bisphosphonates are available. Guidelines for the duration and monitoring of such a drug holiday and the impact of this practice on fracture risk are not yet available.

Adverse Events/Precautions. If oral bisphosphonates are prescribed correctly and the patient takes them correctly, their adverse effects are minimal.[96,97] Patients with creatinine clearances less than 30 to 35 mL/min (0.50–0.58 mL/s), who have serious GI conditions (abnormalities of the esophagus that delay emptying, such as stricture or achalasia), or who are pregnant should not take bisphosphonates. Some experts suggest bisphosphonates can be used in select patients with decreased renal function (see Chapters 52 and 53 on Chronic Kidney Disease).[98]

Weekly and monthly therapies have similar common but less serious GI effects (perforation, ulceration, GI bleeding) than daily therapy. The GI event rates were not increased with concomitant nonsteroidal anti-inflammatory medication use. If GI adverse events occur, switching to a different bisphosphonate might resolve the problem. Patients should be encouraged to discuss GI complaints with a healthcare provider. Intravenous ibandronate and zoledronic acid can be used for patients with GI contraindications or intolerances to oral bisphosphonates. Other common bisphosphonate adverse effects include injection reactions and musculoskeletal pain. Local injection-site reactions and acute phase reactions (e.g., fever, flulike symptoms) can occur but usually diminish with subsequent injections. If severe musculoskeletal pain occurs, the medication can be discontinued for a short term or permanently.

Rare adverse effects include osteonecrosis of the jaw and subtrochanteric femoral (atypical) fractures.[96,97,99] Osteonecrosis of the jaw (ONJ; black box warning) occurs more commonly in patients with cancer, chemotherapy, radiation, and or glucocorticoid therapy receiving higher-dose intravenous bisphosphonate therapy. With oral therapy, about 1 in 100,000 patients might get ONJ.[99] When possible, major dental work should be completed before bisphosphonate initiation. For patients already on therapy, some practitioners withhold bisphosphonate therapy during and after major dental procedures, but no data exist to support any beneficial effect of such practice. For patients with rare and unusual bone fractures while on long-term bisphosphonates, a metabolic bone disease workup should be conducted.

Administration. Before bisphosphonates are used, and especially before intravenous administration, the patient's serum calcium concentrations must be normal. Because bioavailability is very poor for bisphosphonates (<1% to 5%) and to minimize GI side effects, each oral dose should be taken with at least 6 ounces of plain tap water (not coffee, juice, mineral water, or milk) at least 30 (60 for ibandronate) minutes before consuming any food, supplements (including calcium and vitamin D), or medications. The weekly, raspberry-flavored, oral solution needs to be taken with only 2 ounces (~60 mL) of water and can be used for patients with swallowing difficulties (e.g., after stroke, tube feeding). The patient should also remain upright (i.e., either sitting or standing) for at least 30 minutes after alendronate and risedronate and 1 hour after ibandronate administration. A patient who misses a weekly dose can take it the next day. If more than 1 day has lapsed, that dose is skipped until the next scheduled ingestion. If a patient misses a monthly dose, it can be taken up to 7 days before the next administration.

The intravenous products need to be administered by a healthcare provider. The quarterly ibandronate injection comes as a prefilled syringe (3 mg/mL) kit with a butterfly needle. The injection is given intravenously over 15 to 30 seconds. The injection can also be diluted with dextrose 5% in water or normal saline and used with a syringe pump. Once-yearly administration of zoledronic acid should be infused over at least 15 minutes with a pump. Acetaminophen or ibuprofen can be given to decrease acute phase reactions.

Although these medications are effective, adherence is poor and results in decreased effectiveness.[100–102] Although most patients

prefer once-weekly or once-monthly bisphosphonate administration to daily therapy, adherence is still a problem. Even after a hip fracture, bisphosphonate persistence is suboptimal.[103] For patients with adherence issues, the monthly e-mails or postcards sent by the ibandronate manufacturer might be helpful. Intravenous ibandronate and zoledronic acid could be used as replacements if cost is not an issue. Weekly alendronate plus vitamin D can potentially help to ensure better adherence with vitamin D intake.

Mixed Estrogen Agonists/Antagonists 8 Raloxifene, a second-generation mixed estrogen agonist/antagonist (EAA) approved for prevention and treatment of postmenopausal osteoporosis, has estrogenic agonist actions in bone but antagonist actions in breast and uterine tissue (see Table 99–7). Bazedoxifene with and without conjugated equine estrogens[89] and lasofoxifene[104] are newer second-generation EAAs that might be approved soon.

Efficacy. Raloxifene decreases vertebral fractures and increases spine and hip BMD, but to a lesser extent than bisphosphonates (see Table 99–6).[2,3,76,105] Eight-year data support long-term effects and safety in postmenopausal women. After raloxifene discontinuation, the medication effect is lost, with bone loss returning to age- or disease-related rates. For women with severe osteoporosis, particularly when hip fracture risk reduction is desired, a bisphosphonate might be a better choice. Since estradiol is important for bone health in men, some preliminary data have documented benefits of raloxifene in men with hypogonadism and prostate cancer.[37]

Raloxifene has additional benefits that might influence its selection. Raloxifene has an FDA-approved indication for invasive breast cancer risk reduction.[2,105] Thus in a subset of women, this additional benefit might warrant raloxifene use for dual osteoporosis and breast cancer prevention.

Some of the investigational EAAs have also documented breast cancer risk prevention. Raloxifene causes some positive lipid effects (decreased total and low-density lipoprotein cholesterol, neutral effect on high-density lipoprotein cholesterol, slightly increased triglycerides). However, no reduction in cardiovascular effects was demonstrated in the RUTH (Raloxifene Use for the Heart) or MORE-CORE (Multiple Outcomes with Raloxifene study and its continuation) trials.[105]

Adverse Events/Precautions. Hot flushes occur with a greater likelihood in women recently finishing menopause or discontinuing estrogen therapy.[105] Raloxifene rarely causes endometrial bleeding. Raloxifene is contraindicated for women with an active or past history of venous thromboembolic event. Therapy should be stopped if a patient anticipates extended immobility.

In large trials, no change in overall death, cardiovascular death, or overall stroke incidence was seen; however, a slight increase in fatal stroke was documented, resulting in a black box warning.[2,105] Women at high risk for a stroke (e.g., Framingham stroke risk score ≥13)[106] or coronary events and those with known coronary artery disease, peripheral vascular disease, atrial fibrillation, or a prior history of cerebrovascular events might not be good candidates for this medication.

Administration. Similar to bisphosphonates, adherence and persistence problems exist.[102]

Calcitonin Calcitonin is an endogenous hormone released from the thyroid gland when serum calcium is elevated.[107] The prescription product contains salmon calcitonin, which is more potent and longer lasting than the mammalian form. Calcitonin is FDA indicated for osteoporosis treatment for women who are at least 5 years past menopause (see Table 99–7). Because efficacy is less robust than the other antiresorptive therapies, calcitonin is reserved as third-line treatment. Intermittent nasal regimens and an oral product are being explored.

Efficacy. Only vertebral fractures have been documented to decrease with intranasal calcitonin therapy (see Table 99–6).[2,76,107] Calcitonin does not consistently affect hip BMD and does not decrease hip fracture risk.

Calcitonin might provide pain relief to some patients with acute vertebral fractures, about a 2.5-point change on a visual analog scale.[107] If used, calcitonin should be prescribed for short-term (4 weeks) treatment and should not be used in place of other more effective and less expensive analgesics nor should it preclude the use of more appropriate osteoporosis therapy.

Administration. Subcutaneous administration with 100 units daily is available but rarely used because of more adverse effects and costs.

Denosumab Therapy Recently approved; see investigational agents, Tables 99–6 and 99–7, Figure 99–3, and addendum.

Estrogen Therapy Although estrogens are FDA indicated for prevention of osteoporosis, they should only be used short-term in women who need estrogen therapy for the management of menopausal symptoms as the risks of estrogen therapy outweigh the bone benefits.[2,76,108] Even though the Women's Health Initiative trials only assessed one dose of conjugated equine estrogens, most clinicians extrapolate the results to all postmenopausal estrogen therapies until data indicate otherwise.

Efficacy. Hormone therapy (HT)—that is, estrogen with (EPT) or without (ET) a progestogen—significantly decreases fracture risk (see Table 99–6).[2,108] Increases in BMD are less than with bisphosphonates, denosumab, or teriparatide, but greater than with raloxifene and calcitonin. Oral and transdermal estrogens at equivalent doses and continuous or cyclic HT regimens have similar BMD effects. Effect on BMD is dose dependent, with some benefit seen with lower estrogen doses; however, fracture risk reduction has not been demonstrated with the lower doses. When HT is discontinued, bone loss accelerates and fracture protection is lost.

Adverse Events/Precautions/Administration. The lowest effective HT dose that prevents and controls menopausal symptoms is used and discontinued as soon as possible.[108] A complete discussion of adverse events, precautions, and administration for all ET and estrogen and progestogen combination products can be found in Chapter 91.

Testosterone Decreased testosterone concentrations are seen with certain gonadal diseases, eating disorders, glucocorticoid therapy, oophorectomy, menopause, and andropause.

Efficacy. A few studies of testosterone or methyltestosterone replacement in men and women, respectively, have demonstrated increases in BMD, but no data on fracture prevention exist.[34,109] Adding alendronate to testosterone therapy in hypogonadal men improved BMD benefits. Testosterone replacement should not be used solely for the prevention or treatment of osteoporosis, but it might be beneficial to reduce bone loss in patients needing therapy for hypogonadal symptoms or for women with low libido.

Adverse Events/Precaution/Administration. Patients and partners of those using testosterone gel products should be evaluated frequently for adverse events.

Anabolic Therapies

Currently teriparatide is the only available medication that increases bone formation.

Teriparatide Teriparatide is a recombinant product representing the first 34 amino acids in human PTH (see Table 99–7). Teriparatide increases bone formation, the bone remodeling rate, and osteoblast number and activity. Both bone mass and

architecture are improved. Teriparatide is FDA indicated for postmenopausal women, men, and patients on glucocorticoids who are at high risk for fracture. For example, patients who have a history of osteoporotic fracture, multiple risk factors for fracture, very low bone density (e.g., T-score < −3.5), or have failed or are intolerant of previous bisphosphonate therapy could be candidates for PTH therapy. Human PTH (1–31), oral PTH, intranasal PTH, and once-weekly subcutaneous teriparatide administration are being investigated.

Efficacy. Teriparatide reduces vertebral and nonvertebral fracture risk in postmenopausal women (see Table 99–6); however, no fracture data are available in men or for patients taking glucocorticoids.[2,110] Lumbar spine BMD increases are greater than other osteoporosis medications. Although wrist BMD is decreased, wrist fractures are not increased. Discontinuation of teriparatide therapy results in a decrease in BMD, which can be alleviated with subsequent antiresorptive therapy.

Using a second course of teriparatide is controversial. Some advocate no second course.[111] One study found that a second course of teriparatide increased BMD but not to the extent with the first course.[112]

Adverse Events/Precautions. Transient hypercalcemia rarely occurs. A trough serum calcium concentration is recommended 1 month after initiation of therapy. If high (>10.6 mg/mL [>2.65 mmol/L]), calcium intake should be decreased.

Because of an increased incidence of osteosarcoma in rats, teriparatide contains a black box warning against use in patients at increased baseline risk for osteosarcoma (e.g., Paget's bone disease, unexplained elevations of alkaline phosphatase, pediatric patients, young adults with open epiphyses, or patients with prior radiation therapy involving the skeleton).[110] In addition, teriparatide should not be used in patients with hypercalcemia, metabolic bone diseases other than osteoporosis, metastatic or skeletal cancers, or premenopausal women of child-bearing potential.

Administration. Teriparatide is commercially available as a prefilled "pen" delivery device. The pen must be kept refrigerated and can be used immediately after removing from the refrigerator. The subcutaneous injection is delivered to the thigh or abdominal area with site rotation. The administration of the first dose should take place with the patient either sitting or lying down in case orthostatic hypotension occurs. The pen must be discarded 28 days after the initial injection. The patient should be reeducated on correct use with each pen refill.

Teriparatide is the most expensive osteoporosis therapy. Prior authorization may be required. Special arrangements need to be made when patients travel, especially on airplanes.

Combination Therapy

Combination antiresorptive and anabolic therapies have been evaluated with conflicting results.[2,110] Greater increases in BMD have sometimes been demonstrated when a less potent antiresorptive agent, raloxifene or HT, was used with PTH, whereas a blunting of the BMD effect has been seen when combined with alendronate. The effects of other bisphosphonates in combination with PTH might be different as some newer literature is beginning to reveal. This therapeutic issue is still being explored.[113]

Because there is no clear benefit (no documented increased fracture prevention) and there is potential for increased cost, adverse effects, and nonadherence, combination therapy is not recommended.

Investigational Therapies

Besides the aforementioned investigational products, new medication classes are also being developed.

RANKL Inhibitors Denosumab is a fully human monoclonal antibody that binds to RANKL, blocking its ability to bind to its receptor activator of nuclear factor kappa B (RANK) on the surface of osteoclast precursor cells and mature osteoclasts (see Table 99–7). Denosumab inhibits osteoclastogenesis and increases osteoclast apoptosis.

Denosumab was recently approved for select postmenopausal women (see Figure 99–3) and is still being evaluated for chemotherapy-induced osteoporosis. Denosumab 60 mg subcutaneous injection every 6 months for 3 years significantly decreased vertebral fractures by 68%, nonvertebral fractures by 20%, and hip fractures by 40% in postmenopausal women.[89] The same dose improved BMD and decreased new vertebral fractures without significant changes in nonvertebral or clinical vertebral fractures in men receiving androgen deprivation therapy.[114] The BMD effects are at least similar to weekly alendronate and can increase BMD in patients with prior alendronate therapy; however, these studies did not evaluate any fracture outcomes.[115] Activity appears to dissipate upon medication discontinuation.

Adverse effects include back, extremity, and musculoskeletal pain, hypercholesterolemia, cystitis, decreased serum calcium, and skin problems, which were generally similar to placebo or weekly alendronate. Rare, serious adverse effects include serious infections, osteonecrosis of the jaw, and bone turnover suppression.

Other Investigational Medication Classes Additional new classes of medications are beginning to show promise.[13]

Although injectable OPG, a competitive inhibitor of RANKL, blocked osteoclastic differentiation and decreased bone resorption biomarkers in phases I and II, further development has ceased. However, agents to enhance endogenous OPG, decrease RANKL production, or block RANKL binding to receptor activator of nuclear factor kappa B are being developed.

Agents to block osteoclast attachment ($\alpha v\beta_3$ integrin receptor antagonists), inhibit bone matrix degradation (cathepsin K inhibitors, e.g., odanacatib and relacatib), or change osteoclast and osteocyte cell structure (antisclerostin monoclonal antibodies) are in phase I, II, and III clinical trials.

Strontium ranelate and tibolone are approved in Europe, and the latter agent is approved in Canada. Most likely, these two medications will not be marketed in the United States.

VERTEBROPLASTY AND KYPHOPLASTY

Sometimes patients with debilitating pain between 6 and 52 weeks after a vertebral fracture might undergo vertebroplasty or kyphoplasty during which bone cement is injected into the fractured vertebral space.[116] The procedure stabilizes the damaged vertebrae and reduces pain in 70% to 95% of patients. However, not all studies have documented benefit of this procedure, and concerns about long-term outcomes are surfacing.[117] Adverse events are uncommon but include cement leakage into the spinal column, which can result in complicating nerve damage, and vertebral fracturing around the cement.[118]

SPECIAL POPULATIONS

9 Osteoporosis is a particular threat to all age groups and in some subgroups because of genetic abnormalities, diseases, and medications.

CHILDREN

Although rare, osteoporosis in children and adolescents can lead to significant pain, deformity, and chronic disability. Secondary causes

are the main contributors to osteoporosis in children (Tables 99–2 and 99–3).[119] Idiopathic juvenile osteoporosis is a condition that can develop in previously healthy children (mostly between 8 and 12 years of age) and is only diagnosed after the exclusion of all other possible causes of osteoporosis. It can spontaneously resolve after 3 to 5 years, but sequelae can persist into adulthood. Although the pathogenesis is unknown, reduced osteoblastic bone formation mainly in trabecular regions appears to play a primary role.

The diagnosis and treatment of osteoporosis in children and adolescents is challenging. No guidelines or consensus recommendations exist. The International Society for Clinical Densitometry's official position is that the diagnosis of osteoporosis in children (<20 years of age) requires the presence of a clinically significant fracture history (long bone fracture of the lower extremity, vertebral compression fracture, or two or more long bone fractures of the upper extremities) in combination with low bone mass.[120] Low bone mass is defined as a Z-score below a –2.0 (adjusted for body size and ethnicity/race) using central DXA of the spine or total body.

After correcting any underlying causes and instituting a bone-healthy lifestyle, pharmacologic treatment should be considered for children with low bone mass and low trauma fractures.[121] Several small studies, mostly evaluating the intravenous bisphosphonate pamidronate or oral alendronate, have demonstrated increases in BMD. No studies have demonstrated fracture efficacy in this population. The optimal medication, dose, and duration of therapy are unknown, and more safety data are needed. A major concern with bisphosphonates is their effect on longitudinal bone growth and modeling; however, fracture healing, skeletal growth/maturation, or the appearance of growth plates does not appear to be impaired. Teriparatide cannot be used in children as it has a black box warning indicating an increased risk for osteosarcoma.

PREMENOPAUSAL WOMEN

Clinically significant bone loss and fractures in healthy premenopausal women are rare.[122] Approximately 15% of healthy premenopausal women will have low BMD as a normal variation of peak bone mass. Low peak bone mass is a major risk factor for postmenopausal osteoporosis and fractures but thus far is not a predictor of an increased risk for fractures in the premenopausal years. This might be a result of better bone architecture contributing to better bone strength in younger women.

Routine bone density screening and testing are not cost effective and should not be performed in healthy premenopausal women. No evidence supports that identifying low bone density in healthy premenopausal women results in improved bone-healthy lifestyle practices nor does any evidence exist to support that pharmacologic treatment will reduce future fracture risk in this population.

Most premenopausal women with osteoporosis (Z-score < –2.0) or a history of low trauma fracture have an identifiable secondary cause (see Tables 99–2 and 99–3). Therefore, premenopausal women presenting with a history of low-trauma fracture or with a suspected secondary cause for osteoporosis should undergo central DXA testing; if BMD is low, the patient should be considered for pharmacologic therapy. Women with an unidentified cause for osteoporosis and no history of fracture should be treated with a bone-healthy lifestyle and watchful waiting.

Pharmacologic therapy for osteoporosis should be used with caution in premenopausal women as efficacy and safety have not been adequately demonstrated. The oral bisphosphonates, intravenous ibandronate, calcitonin, and teriparatide are in pregnancy category C. Zoledronic acid is in pregnancy category D. Raloxifene is in pregnancy category X.

Bisphosphonates are incorporated into the bone matrix and slowly released over time. A theoretical concern is a risk for fetal harm with pregnancies that occur during and after therapy has been stopped. While limited case reports have documented healthy infants after bisphosphonate use, more safety data are needed.

THE "OLDER" SENIOR

Osteoporosis and adverse outcomes from fractures increase with age.[16,39] Age is an independent risk factor for osteoporosis and osteoporotic fractures, with the prevalence increasing dramatically with age. Seniors are living longer. The average additional life span for an 85-year-old was 6.8 years in 2003 and it is estimated that the number of people in the United States age 85 years and older will increase from 5.1 million in 2004 to 7.3 million by 2020. The number of "older" seniors with osteoporosis is on the rise, yet the condition is vastly underdiagnosed and undertreated in this population.

Central DXA BMD testing is cost-effective in the older senior. If central DXA testing is not feasible (e.g., patient is institutionalized), heel or forearm testing using a portable quantitative ultrasound or peripheral DXA device can be used for risk stratification. Alternatively, calculation of the 10-year probability for hip or major osteoporotic fracture using FRAX can possibly be used.

Older seniors should practice a bone-healthy lifestyle, ingest adequate calcium and vitamin D, and implement measures to prevent falls. When deciding whether or not to use prescription medications in older seniors, the following factors need to be taken into consideration: remaining life span, ability to take and afford medications, cognitive function, GI disorders, polypharmacy, desire to avoid additional medications, and regimen complexity. Although efficacy and safety data are limited in the older senior, evidence consistently shows that those at highest risk for fracture benefit most from pharmacologic therapy.

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

⓾ Glucocorticoids are the most common secondary cause of osteoporosis and the third most common cause of osteoporosis overall.[32] Approximately 30% to 50% of patients taking chronic oral glucocorticoids will experience a fracture. Bone losses are rapid, with the greatest decrease occurring in the first 6 to 12 months of therapy. Low to medium doses of inhaled glucocorticoids have no appreciable effect on bone density and fracture risk. The impact of long-term, high-dose inhaled glucocorticoids needs further evaluation.

The pathophysiology of glucocorticoid-induced osteoporosis (GIO) is multifactorial. Glucocorticoids decrease bone formation through decreased proliferation and differentiation, and enhanced apoptosis of osteoblasts.[12,32] They can interfere with the bone's natural repair mechanism through increased apoptosis of osteocytes, the bone's communication cells. Glucocorticoids increase bone resorption by increasing RANKL and decreasing OPG. They can reduce estrogen and testosterone concentrations and create a negative calcium balance by decreasing calcium absorption and increasing urinary calcium excretion. The underlying disease processes might also contribute negatively to bone metabolism.

The 2001 American College of Rheumatology guidelines provide direction and are being updated.[123] A baseline BMD using central DXA is recommended for all patients starting on 5 mg or more daily of prednisone equivalent for at least 6 months. BMD testing should also be considered at baseline in patients being started on shorter durations of systemic glucocorticoids if they are at high risk for low bone mass and fractures based on risk factors (e.g., age >65 years, postmenopausal, current smoker, and personal history of a

low trauma fracture as an adult). Because of the rapid loss of bone that can occur with oral glucocorticoid therapy, central DXA can be repeated every 6 to 12 months if needed. Patients using high-dose inhaled corticosteroids should be evaluated for low bone mass or osteoporosis.

In addition to a bone-healthy lifestyle, pharmacologic therapy is required.[123,124] All patients starting or receiving long-term systemic glucocorticoid therapy should ingest 1,500 mg elemental calcium and 800 to 1,200 units of vitamin D daily and practice a bone-healthy lifestyle. Oral alendronate and risedronate and intravenous zoledronic acid have documented efficacy and are FDA indicated for GIO. The guidelines recommend all patients newly starting on systemic glucocorticoids (≥5 mg/day of prednisone equivalent) for an anticipated duration of at least 3 months should receive preventive bisphosphonate therapy.

Zoledronic acid is approved for patients with an anticipated steroid duration of at least 1 year. A more conservative approach might be considered in premenopausal women of child-bearing potential.

Bisphosphonate therapy is also recommended for patients starting or receiving long-term glucocorticoid therapy with documented low bone density (T-score < −1.0) or evidence of a low-trauma fracture.

Teriparatide is the only anabolic therapy commercially available that increases bone formation. Teriparatide can be used if bisphosphonates are not tolerated or are contraindicated.

Testosterone replacement therapy may be considered in men, and high-dose hormonal oral contraceptives for premenopausal women with documented hypogonadism.

TRANSPLANTATION OSTEOPOROSIS

Patients undergoing solid-organ transplantation (e.g., kidney, lung, heart, and liver) have a high risk for osteoporosis and osteoporotic fractures.[125] Prior to transplantation, many patients have osteoporosis or low BMD because of osteoporosis risk factors (see **Table 99–1**) and negative bone effects from their underlying diseases (e.g., alcoholism, cachexia, impaired liver or kidney function, hypogonadism, and deconditioning) and medications (see **Tables 99–2** and **99–3**). After transplantation, bone loss and fracture risk increase dramatically within the first 6 to 12 months, mainly as a consequence of high-dose systemic glucocorticoid exposure and the use of calcineurin inhibitors (e.g., cyclosporine). Sometimes bone loss slows or improves within 1 year of transplant.

Before transplantation, patients should be evaluated for metabolic bone disease with lab tests and physical examination for secondary causes (see **Tables 99–2** and **99–3**), radiographs for vertebral fractures, and central DXA.[125] Regardless of BMD results, patients should be counseled on a bone-healthy lifestyle and instructed to take 1,000 to 1,200 mg of elemental calcium and 800 to 1,000 units of vitamin D daily to maintain sufficient concentrations. Calcitriol (1,25-dihydroxyvitamin D) at a dose of 0.5 mcg daily might be needed for renal and/or liver dysfunction. Pretransplant patients with osteoporosis or a low trauma fracture, except patients with end-stage renal disease awaiting kidney transplantation, should be started on bisphosphonate therapy. In patients with normal BMD prior to transplant, short-term bisphosphonate therapy (6 – 12 months) can be used to prevent bone loss after transplant. PTH has not been studied in the transplant population and is contraindicated in kidney transplant patients with secondary hyperparathyroidism. Testosterone replacement might be considered for men, and high-dose hormonal oral contraceptives are options for premenopausal women with hypogonadism. Central DXA can be repeated as early as 6 to 12 months to evaluate bone loss and the effects of treatment.

CHRONIC KIDNEY DISEASE

Chronic kidney disease is defined as kidney damage for at least 3 months with or without a decrease in glomerular filtration rate (GFR) or a GFR less than 60 mL/min/1.73 m^2 (0.58 mL/s/m^2) for at least 3 months with or without kidney damage. In patients with a creatinine clearance (CrCl) greater than 30 mL/min (0.50 mL/s), osteoporosis can be managed routinely (see **Fig. 99–3**). As noted in FDA-approved product labeling, bisphosphonates are not recommended for patients with CrCl less than 30 or 35 mL/min (0.50 or 0.58 mL/s) because of potential drug accumulation. Newer data suggest that differences in the origin of chronic kidney disease, either intrinsic kidney damage or aging, might influence safety of these medications in those with age-related chronic kidney disease.

Based on large retrospective or pooled studies, oral bisphosphonates (CrCl as low as 15 mL/min [0.25 mL/s]), raloxifene (CrCl <45 mL/min [0.75 mL/s]), and teriparatide (CrCl as low as 30 – 49 mL/min [0.50 – 0.82 mL/s]) appear safe and efficacious in patients with age-related declines in renal function.[126,127] Some experts recommend decreasing dose by 50% or extending the dosing interval, and using the agent for less than 3 years.[98]

Renal osteodystrophy describes a constellation of metabolic bone disorders that develop in patients with stages 4 and 5 chronic kidney disease (GFR <30 mL/min/1.73 m^2 [<0.29 mL/s/m^2]) as a consequence of intrinsic kidney damage. Bone biopsy might be necessary to differentiate the different types of renal osteodystrophy from osteoporosis in this population. Antiresorptive therapies would be appropriate for the management of osteoporosis; however, they are contraindicated in patients with osteomalacia or adynamic bone and may be ineffective for osteitis fibrosa cystica.[126]

GASTROINTESTINAL DISEASES

The three most common gastrointestinal disorders associated with increased osteoporosis risk are inflammatory bowel disease, celiac disease, and postgastrectomy states.[77] Impaired absorption of key nutrients and minerals, chronic systemic glucocorticoid use, and increased levels of inflammatory cytokines are implicated.[128] The role of proinflammatory cytokines needs further investigation.

The prevalence of osteoporosis in patients with inflammatory bowel disease (e.g., Crohn's disease or ulcerative colitis) ranges from 17% to 41%, and the relative risk for fracture is approximately 40% higher than that for the general population.[77,128] When glucocorticoids are used, the GIO prevention and treatment guidelines should be followed.[123]

Celiac disease is an inherited autoimmune disorder in which the ingestion of the protein gluten triggers an immune reaction that damages the mucosal lining of the small intestine and leads to impaired nutrient absorption.[129] Approximately 1% of the population has celiac disease, with women having twice the incidence of men. Low bone density is seen in up to 70% of patients with celiac disease. Long-term fracture risk is estimated to be double that of the general population.[77] Impaired nutrient absorption, especially calcium and vitamin D, plays a central role in the bone loss, requiring 25(OH) vitamin D monitoring. Celiac disease management requires a gluten-free diet, which can significantly increase BMD by approximately 5% within 1 year.[77,130]

Patients undergoing total or partial gastrectomy are at high risk for osteoporosis. The incidence of osteoporosis may be as high as 32% to 42% with a 30-year cumulative risk for fracture of 72% in women and 48% in men.[77] Although the pathophysiology of bone disease in postgastrectomy is unknown, reduced nutritional intake of protein might play a role. Bone density evaluation using central DXA should be considered in all patients who are more than 10 years postgastrectomy.

PHARMACOECONOMIC CONSIDERATIONS

The estimated burden for fractures in 2005 was $17 billion and is expected to increase to $25 billion by 2025.[7] Consequently, determining who should be screened and treated for osteoporosis and fracture prevention is important. Various studies use different assumptions in their models.

Pharmacoeconomic considerations were used to determine 3% as the 10-year probability of hip fracture as a decision point in the NOF guidelines for which patients with low bone mass to treat.[131] The value of $60,000 per quality-adjusted life-year was the cut point for cost-effectiveness. Sensitivity analysis was conducted for age, sex, and race/ethnicity, yielding similar results.

Preventing osteoporosis in postmenopausal women with normal or osteopenic BMD is not cost-effective.[132] However, screening older women and only using a bisphosphonate for those with osteoporosis is cost-effective.[133] The cost per quality-adjusted life-year decreased from $40,100 for women 65 to 74 years old to a cost savings for women 85 years and older.

For men, screening and treating men after the age of 65 years with a low-trauma fracture and screening and treating men 80- to 85-years-old without a previous fracture were cost-effective when therapy costs were assumed to be $1,000 annually.[134] With generic medications, screening at a lower older age in men might be warranted based on cost savings. In a different senior study, bisphosphonates were found to produce the greatest gain in quality-adjusted life-years at the lowest cost (i.e., 0.0637; $4,200), followed by PTH (0.0574; $6,833), calcitonin (0.0348; $5,761), and raloxifene (0.0339; $5,676).[135]

EVALUATION OF THERAPEUTIC OUTCOMES

Besides monitoring for efficacy and safety, adherence evaluation should also be conducted.

MONITORING OF THE PHARMACEUTICAL CARE PLAN

Central DXA BMD measurements can be obtained every 1 to 2 years for monitoring bone loss and every 2 years for assessing treatment response.[5] In patients with conditions associated with higher rates of bone loss (e.g., glucocorticoid use), more frequent monitoring might be warranted.

To minimize test variability, BMD testing should be performed on the same DXA machine. A negative change in absolute BMD that exceeds the precision error of the machine at that site (approximately 3% for spine and 4% for hip) is considered a clinically significant BMD loss and warrants further investigation. Because changes in BMD do not entirely explain changes in fracture risk, many experts believe that decisions on whether or not to continue a particular therapy should not be based solely on BMD response.

Biochemical markers of bone turnover have been evaluated for use in monitoring early responses to medications, especially for identifying therapy nonresponders or possibly promoting adherence.[51,52] Bone resorption markers, with the first or second morning void for urinary N-terminal crosslinking telopeptide of type 1 collagen or morning for serum C-terminal crosslinking telopeptide of type 1 collagen, are typically performed after an overnight fast at baseline and repeated after 3 to 6 months of therapy. These parameters will decrease with effective therapy. Circadian variability, seasonal variations, food intake, and recent exercise can all impact results. Because no consensus on result interpretation and high test variability exist, these tests are not yet considered routine.

PHARMACY SERVICES

9 Pharmacists play an important role in screening and monitoring for osteoporosis. Community pharmacy screenings with ultrasonography identify patients who are at risk, and consultations with a pharmacist or other healthcare professional can increase lifestyle changes, medication use, and DXA referrals. This practice has been financially sustainable in the community pharmacy setting.[136] Since adherence is strongly linked to fracture prevention,[100,101] pharmacists should help identify and resolve medication-related problems that are affecting adherence for patients taking antiosteoporotic medications.

Pharmacists can also increase use of these medications after a low-trauma fracture by using databases to identify undertreated patients. They can increase diagnostic testing and osteoporosis prevention/treatment, and identify and resolve medication and disease causes of bone loss, especially in special patient populations at greater risk.

OTHER METABOLIC BONE DISORDERS

Because of increased interest in bone diseases and newer medications, better therapies are being explored and developed for other bone diseases.

OSTEOMALACIA

Osteomalacia, meaning "soft bones," is a condition seen in adults in which the bone is significantly undermineralized. Rickets is the childhood equivalent of osteomalacia. The most common cause of osteomalacia is severe, prolonged vitamin D deficiency. Disorders that cause hypophosphatemia and, rarely, medications such as long-term anticonvulsant therapy can also cause osteomalacia.[50]

Patients with osteomalacia present with pathologic fractures and/or deep bone pain, proximal muscle weakness, or no obvious symptoms but low BMD. Patients with osteomalacia will have an extremely low 25(OH) vitamin D concentration (<10 ng/mL [<25 nmol/L]) and might have an elevated bone-specific alkaline phosphate and hypocalcemia. The treatment of osteomalacia caused by vitamin D deficiency is high-dose vitamin D replacement therapy. Prescription oral ergocalciferol 50,000 units once to twice weekly for at least 8 weeks is a regimen that is frequently used to raise vitamin D concentrations into the sufficient range. Other high-dose oral and intramuscular vitamin D regimens have also been used. Once 25(OH) vitamin D concentrations are greater than 30 ng/mL (75 nmol/L), chronic maintenance vitamin D therapy can be instituted. Oral ergocalciferol 50,000 units once or twice a month or nonprescription cholecalciferol at least 1,000 units up 2,000 units once daily are reasonable maintenance options.

PAGET'S DISEASE

Unlike osteoporosis, which is a systemic disorder affecting the entire skeleton, Paget's disease is a disorder of bone remodeling in discrete sections of bone. The main areas affected are the skull, spine, pelvis, femur, and tibia.[137] In this condition, the osteoclasts are abnormally large and have heightened activity, increasing the bone turnover rate and affecting both bone resorption and formation. The accelerated bone formation does not allow for proper layering of collagen, leading to disorganized or woven bone. The disease is usually asymptomatic; however, patients can experience bone pain, headaches with skull involvement, fractures, skeletal deformities, and, rarely, malignant transformation into osteosarcoma.

Paget's disease tends to occur in adults 50 years and older, with a slight predominance in men and patients of north European ancestry.[137] The disease affects approximately 1% to 2% of adults. Various environmental and genetic factors cause Paget's disease, with viral causes a controversial pathogenesis. Paget's disease is typically discovered because of an unexplained elevation in serum alkaline phosphatase or classic bone findings on routine x-ray films.

Bisphosphonates are the medication of choice for managing Paget's disease because they work directly on osteoclasts to slow down bone turnover, allowing more time for proper bone formation.[137,138] Six bisphosphonates are FDA indicated for the treatment of Paget's disease. Calcium and vitamin D deficiencies need to be corrected before beginning bisphosphonate therapy. The most commonly used regimens are risedronate 30-mg tablet orally once daily for 2 months; pamidronate 60-mg intravenous infusion over 4 hours for 3 consecutive days; alendronate 40-mg tablet orally once daily for 6 months, and a one-time intravenous infusion of 5-mg zoledronic acid.

Zoledronic acid and risedronate regimens were compared in a head-to-head study, with zoledronic acid demonstrating a superior and more rapid and sustained therapeutic response.[139] Demonstrated efficacy and convenience make zoledronic acid a good initial choice for most patients. Relapse after treatment is common (e.g., 28% in 5 years). Therapy can be repeated if symptoms return or serum alkaline phosphatase increases by 25% or more.

Subcutaneous or intramuscular salmon calcitonin is an approved option if bisphosphonate therapy is contraindicated. Analgesics, anti-inflammatory medications, and some forms of alternative healing might be needed to treat the pain symptoms.

CONCLUSIONS

Osteoporosis is a public health priority, as the prevalence of both the disease and fracture incidence is expected to increase in the next 10 to 20 years because of the increasing age of the population in many countries. Osteoporosis prevention begins at birth and continues throughout life by practicing a bone-healthy lifestyle (adequate calcium and vitamin D intake, exercise, no smoking, minimal alcohol use, and fall prevention). Generally osteoporosis occurs in postmenopausal women and senior men; however, the disease can occur in all ages as a result of secondary causes such as genetics, diseases, and medications. Portable ultrasonography machines can screen for osteoporosis but central bone densitometry (DXA) is used for diagnosis and monitoring.

Bisphosphonates are the medication class of choice because they decrease hip, nonvertebral, and vertebral fractures, are relatively safe, and are affordable. Teriparatide is the only medication that can build bone; however, cost and subcutaneous administration limit its use. Although medications decrease fracture risk, prescribing of antiosteoporotic and preventive medications and adherence to such therapy is low. Suboptimal medication adherence is documented to decrease fracture prevention outcomes.

As osteoporosis management becomes more streamlined for postmenopausal women, practitioners are not only identifying other special populations at risk for osteoporosis (e.g., men, transplantation patients, glucocorticoid therapy, cancer therapies) but determining the best strategies for osteoporosis prevention and treatment. New agents and medication classes to prevent and treat osteoporosis show promise.

Other bone disorders, especially those related to vitamin D insufficiency and deficiency can be improved or eliminated with appropriate medications. Since most people are low in vitamin D, patients at risk for or with symptoms of bone disorders should have a 25(OH) vitamin D level drawn, with appropriate replenishment and maintenance vitamin D therapy instituted.

ADDENDUM

Denosumab was approved after this chapter was completed. Additional information includes serum calcium needs to be normal and major dental work should be completed before use. The product is a refrigerated prefilled pen that can be at room temperature up to 14 days before administration. Also available is a single use vial. Injection can be given in the upper arm, upper thigh, and abdomen.

Because of concerns about serious side effects, a medication guide, as part of the Risk Evaluation and Mitigation Strategy (REMS), is given to the patients. All providers are encouraged to participate in the an optional Postmarketing Active Surveillance Program to evaluate adverse effects. The prescriber can delegate this monitoring to other healthcare professionals, which could be a pharmacist including pharmacists.

ABBREVIATIONS

25(OH) vitamin D: calcidiol/25-hydroxyvitamin D

BMD: bone mineral density

DXA: dual-energy x-ray absorptiometry

EAA: estrogen agonist antagonist

EPT: estrogen progestogen therapy

ET: estrogen therapy

FRAX: World Health Organization fracture risk assessment tool

GFR: glomerular filtration rate

GI: gastrointestinal

GIO: glucocorticoid-induced osteoporosis

HT: hormone therapy (estrogen with or without a progestogen)

OPG: osteoprotegerin

PTH: parathyroid hormone

RANKL: receptor activator of nuclear factor-kappa B ligand

WHO: World Health Organization

CHAPTER 100

Rheumatoid Arthritis

ARTHUR A. SCHUNA

KEY CONCEPTS

1. Rheumatoid arthritis (RA) is a systemic disease characterized by symmetrical inflammation of joints yet may involve other organ systems.
2. Control of inflammation is the key to slowing or preventing disease progression as well as managing symptoms.
3. Drug therapy should be only part of a comprehensive program for patient management which would also include physical therapy, exercise, and rest. Assistive devices and orthopedic surgery may be necessary in some patients.
4. Disease-modifying antirheumatic drugs (DMARDs) or biologic agents should be started within 3 months of the diagnosis of RA.
5. Nonsteroidal antiinflammatory drugs and/or corticosteroids should be considered adjunctive therapy early in the course of treatment and as needed if symptoms are not adequately controlled with DMARDs.
6. When DMARDs used singly are ineffective or not adequately effective, combination therapy with two or more DMARDs or a DMARD plus biologic agent may be used to induce a response.
7. Patients require careful monitoring for toxicity and therapeutic benefit for the duration of treatment.

Rheumatoid arthritis (RA) is the most common systemic inflammatory disease characterized by symmetrical joint involvement. Extraarticular involvement, including rheumatoid nodules, vasculitis, eye inflammation, neurologic dysfunction, cardiopulmonary disease, lymphadenopathy, and splenomegaly, can be manifestations of the disease. Although the usual disease course is chronic, some patients will enter a remission spontaneously.

EPIDEMIOLOGY

Rheumatoid arthritis is estimated to have a prevalence of 1% and does not have any racial predilections. It can occur at any age, with increasing prevalence up to the seventh decade of life. The disease is 3 times more common in women. In people ages 15 to 45 years, women predominate by a ratio of 6:1; the sex ratio is approximately equal among patients in the first decade of life and in those older than age 60 years.

Epidemiologic data suggest that a genetic predisposition and exposure to unknown environmental factors may be necessary for expression of the disease. The major histocompatibility complex molecules, located on T lymphocytes, appear to have an important role in most patients with RA. These molecules can be characterized using human lymphocyte antigen (HLA) typing. A majority of patients with RA have HLA-DR4, HLA-DR1, or both antigens in the major histocompatibility complex region. Patients with HLA-DR4 antigen are 3.5 times more likely to develop RA than those patients who have other HLA-DR antigens.[1] Although the major histocompatibility complex region is important, it is not the sole determinant, because patients can have the disease without these HLA types. Rheumatoid arthritis is 6 times more common among dizygotic twins and nontwin children of parents with rheumatoid factor-positive, erosive rheumatoid arthritis when compared with children whose parents do not have the disease. If one of a pair of monozygotic twins is affected, the other twin has a 30 times greater risk of developing the disease.[2,3]

PATHOPHYSIOLOGY

1 Chronic inflammation of the synovial tissue lining the joint capsule results in the proliferation of this tissue. The inflamed, proliferating synovium characteristic of rheumatoid arthritis is called *pannus*. This pannus invades the cartilage and eventually the bone surface, producing erosions of bone and cartilage and leading to destruction of the joint. The factors that initiate the inflammatory process are unknown.

The immune system is a complex network of checks and balances designed to discriminate self from non-self (foreign) tissues. It helps rid the body of infectious agents, tumor cells, and products associated with the breakdown of cells. In rheumatoid arthritis, this system no longer can differentiate self from non-self tissues and attacks the synovial tissue and other connective tissues.

The immune system has both humoral and cell-mediated functions (Fig. 100–1). The humoral component is necessary for the formation of antibodies. These antibodies are produced by plasma cells, which are derived from B lymphocytes. Most patients with RA form antibodies called *rheumatoid factors*. Rheumatoid factors have not been identified as pathogenic, nor does the quantity of these circulating antibodies always correlate with disease activity. Seropositive patients tend to have a more aggressive course of their illness than do seronegative patients. Immunoglobulins can activate the complement system. The complement system amplifies the immune response by encouraging chemotaxis, phagocytosis, and

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

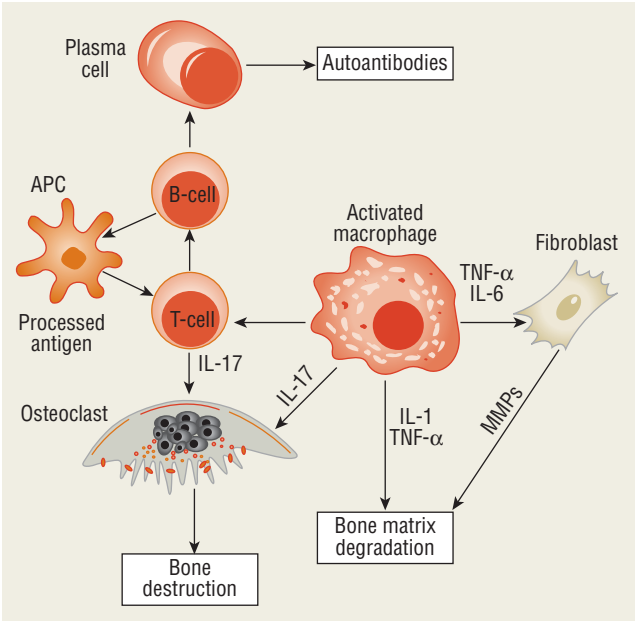

FIGURE 100-1. Pathogenesis of the inflammatory response. Antigen-presenting cells process and present antigens to T cells which may stimulate B cells to produce antibodies and osteoclasts to destroy and remove bone. Macrophages stimulated by the immune response can stimulate T cells and osteoclasts to promote inflammation. They also can stimulate fibroblasts which produce matrix metalloproteinases to degrade the bone matrix and produce proinflammatory cytokines. Activated T cells and macrophages release factors that promote tissue destruction, increase blood flow, and result in cellular invasion of synovial tissue and joint fluid. (APC, antigen-presenting cell; MMP, matrix metalloproteinase; IL, interleukin; TNF-α, tumor necrosis factor α.)

the release of lymphokines by mononuclear cells, which are then presented to T lymphocytes. The processed antigen is recognized by major histocompatibility complex proteins on the lymphocyte, which activates it to stimulate the production of T and B cells. The proinflammatory cytokines tumor necrosis factor (TNF), interleukin (IL)-1 and IL-6 are key substances in the initiation and continuance of rheumatoid inflammation. Lymphocytes may be either B cells (derived from bone marrow) or T cells (derived from thymus tissue). T cells may be either $CD4^+$ (T-helper) or $CD8^+$ (cytotoxic or killer) T cells. There are two subtypes of T-helper cells: TH_1, which promote inflammation by producing interferon-γ, tumor necrosis factor, and IL-2; and TH_2, which produce the antiinflammatory cytokines IL-4, IL-5, and IL-10. In addition to TH_1-TH_2, a third type of T cell has been identified known as TH_{17}. It can produce IL-17. IL-17 can induce proinflammatory cytokines in fibroblasts and synoviocytes and stimulate the release of matrix metalloproteinases and other cytotoxic substances which leads to cartilage destruction. $CD8^+$ killer T cells have a regulatory effect on the immune process by suppressing activity of $CD4^+$ cells through release of antiinflammatory cytokines and promoting apoptosis (cell death). Activated T cells produce cytotoxins, which are directly toxic to tissues, and cytokines, which stimulate further activation of inflammatory processes and attract cells to areas of inflammation. Macrophages are stimulated to release prostaglandins and cytotoxins.[4–6] T-cell activation requires both stimulation by proinflammatory cytokines as well as interaction between cell surface receptors, called co-stimulation. One of these costimulation interactions is between CD28 and CD80/86. The binding of the CD80/86 receptor by abatacept has proved to be an effective treatment for RA but preventing costimulation interactions between T cells.[7]

Although it has been suggested that T cells play a key role in the pathogenesis of RA, B cells clearly have an equally important role. Evidence for this importance may be found in the effectiveness of B-cell depletion using rituximab in controlling rheumatoid inflammation. Activated B cells produce plasma cells, which form antibodies. These antibodies in combination with complement result in the accumulation of polymorphonuclear leukocytes, which release cytotoxins, oxygen free radicals, and hydroxyl radicals that promote cellular damage to synovium and bone. The benefits of B-cell depletion occur even though antibody formation is not suppressed with rituximab therapy suggesting other mechanisms play a role in reducing RA activity. B cells produce cytokines that may alter the function of other immune cells, and they also have the ability to process antigens and act as antigen-presenting cells, which interact with T cells to activate the immune process.[8–11]

In the synovial membrane, $CD4^+$ T cells are abundant and communicate with macrophages, osteoclasts, fibroblasts and chondrocytes either through direct cell–cell interactions using cell surface receptors or through proinflammatory cytokines such as TNF-α, IL-1, and IL-6. These cells produce metalloproteinases and other cytotoxic substances, which lead to the erosion of bone and cartilage. They also release substances promoting growth of blood vessels and adhesion molecules, which assists in proinflammatory cell trafficking and attachment of fibroblasts to cartilage and eventual synovial invasion and destruction.[12–14]

Vasoactive substances also play a role in the inflammatory process. Histamine, kinins, and prostaglandins are released at the site of inflammation. These substances increase both blood flow to the site of inflammation and the permeability of blood vessels. These substances cause the edema, warmth, erythema, and pain associated with joint inflammation and make it easier for granulocytes to pass from blood vessels to the site of inflammation.

CLINICAL PRESENTATION OF RHEUMATOID ARTHRITIS

Symptoms

- Joint pain and stiffness of more than 6 weeks' duration. May also experience fatigue, weakness, low-grade fever, loss of appetite. Muscle pain and afternoon fatigue may also be present. Joint deformity is generally seen late in the disease.

Signs

- Tenderness with warmth and swelling over affected joints usually involving hands and feet. Distribution of joint involvement is frequently symmetrical. Rheumatoid nodules may also be present.

Laboratory Tests

- Rheumatoid factor (RF) detectable in 60% to 70%.
- Anticyclic citrullinated peptide (anti-CCP) antibodies have similar sensitivity to RF (50%–85%) but are more specific (90%–95%) and are present earlier in the disease.
- Elevated erythrocyte sedimentation rate and C-reactive protein are markers for inflammation.
- Normocytic normochromic anemia is common as is thrombocytosis.

Other Diagnostic Tests

- Joint fluid aspiration may show increased white blood cell counts without infection, crystals.
- Joint radiographs may show periarticular osteoporosis, joint space narrowing, or erosions.

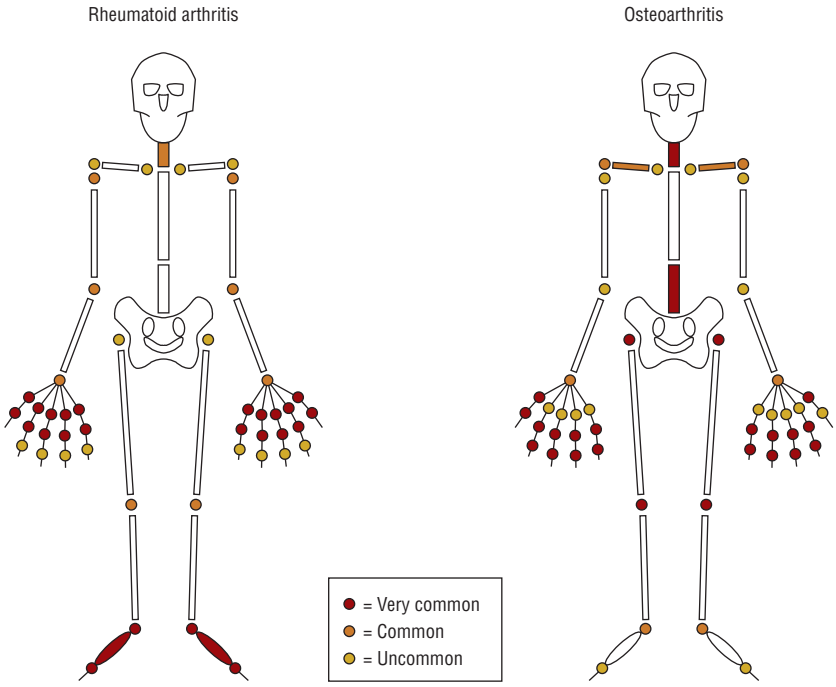

FIGURE 100-2. Patterns of joint involvement in rheumatoid arthritis and osteoarthritis.

The end results of the chronic inflammatory changes are variable. Loss of cartilage may result in a loss of the joint space. The formation of chronic granulation or scar tissue can lead to loss of joint motion or bony fusion (called *ankylosis*). Laxity of tendon structures can result in a loss of support to the affected joint, leading to instability or subluxation. Tendon contractures also may occur, leading to chronic deformity.[12,15]

The symptoms of RA usually develop insidiously over the course of several weeks to months. Prodromal symptoms include fatigue, weakness, low-grade fever, loss of appetite, and joint pain. Stiffness and muscle aches (myalgias) may precede the development of joint swelling (synovitis). Fatigue may be more of a problem in the afternoon. During disease flares, the onset of fatigue begins earlier in the day and subsides as disease activity lessens. Most commonly, joint involvement tends to be symmetrical; however, early in the disease some patients present with an asymmetrical pattern involving one or a few joints that eventually develops into the more classic presentation. Approximately 20% of patients develop an abrupt onset of their illness with fevers, polyarthritis, and constitutional symptoms (e.g., depression, anxiety, fatigue, anorexia, and weight loss).[2,3]

No single test or physical finding can be used to make the diagnosis of RA. In early disease the diagnosis can be particularly challenging given that radiographic findings are usually not found and rheumatoid factor test can be undetectable. Duration of joint pain and swelling and morning stiffness lasting more than 1 hour and involvement of three or more joints are important early predictors of the development of persistent erosive rheumatoid arthritis.[16]

JOINT INVOLVEMENT

The joints affected most frequently by rheumatoid arthritis are the small joints of the hands, wrists, and feet (Fig. 100–2). In addition, elbows, shoulders, hips, knees, and ankles may be involved. Patients usually experience joint stiffness that typically is worse in the morning. The duration of stiffness tends to be correlated directly with disease activity, usually exceeds 30 minutes, and may persist all day. Chronic inflammation with lack of an adequate exercise program results in loss of range of motion, atrophy of muscles, weakness, and deformity (Figs. 100–3 and 100–4).

On examination, the swelling of the joints may be visible or may be apparent only by palpation. The swelling feels soft and spongy because it is caused by proliferation of soft tissues or fluid accumulation within the joint capsule. The swollen joint may appear erythematous and feel warmer than nearby skin surfaces, especially early in the course of the disease. In contrast, the swelling associated with osteoarthritis usually is bony (caused by osteophytes) and infrequently is associated with signs of inflammation.

Involvement of the hands and wrists is common in RA. Hand involvement is manifested by pain, swelling, tenderness, and grip weakness during the acute phase and by subluxation, instability, deformity, and muscle atrophy in the chronic phase of the disease. Functional difficulties with clasp, grasp, and pinch alter both strength and fine motor movement.

Deformity of the hand may be seen with chronic inflammation. These changes may alter the mechanics of hand function reducing grip strength and making it difficult to perform usual daily activity.

Pain in the elbow and shoulder may be the result of true joint inflammation or inflammation of soft-tissue structures such as tendons (tendonitis) or the bursa (bursitis). The knee also can be involved, with loss of cartilage, instability, and joint pain. Synovitis of the knee may cause the formation of a cyst behind the knee called a *popliteal* or *Baker cyst*. These cysts may become painful as they get tense, or they may rupture, producing a clinical picture similar to thrombophlebitis secondary to the release of inflammatory components into the area of the calf muscle (pseudothrombophlebitis syndrome). Chronic joint pain leads to muscle atrophy, which can result in a laxity of the ligamentous structures that support the knee, causing instability. Maintenance of an adequate range of motion of the knee is essential to normal gait.

Foot and ankle involvement in RA is common. The metatarsophalangeal joints are involved frequently in RA, making walking difficult. Subluxation of the metatarsal heads leads to "cock-up" or hammer toe deformities. Subluxation also may cause a flexion deformity at the proximal interphalangeal joint of the toe, leading to pressure necrosis of the skin over the joint secondary to irritation caused by shoes. Hallux valgus (lateral deviation of the digit) and bunion or callus formation may occur at the great toe. A widening of the foot occurs commonly with long-standing disease.

Involvement of the spine usually occurs in the cervical vertebrae; lumbar vertebral involvement is rare. Involvement of the first and second cervical vertebrae (C1–C2) can lead to instability of this joint. Patients with this problem are at a greater risk for spinal cord compression, although this complication is rare.

The temporomandibular joint (jaw) can be affected, resulting in malocclusion and difficulty in chewing food. Inflammation of cartilage in the chest can lead to chest wall pain. Hip pain may occur as a result of destructive changes in the hip joint, soft-tissue inflammation (e.g., bursitis), or referred pain from nerve entrapment at the lumbar vertebrae.

EXTRAARTICULAR INVOLVEMENT

Although joint involvement in RA is a hallmark finding in rheumatoid arthritis, it is important to recognize that, as a systemic disease, other organ systems are often involved.

Rheumatoid Nodules

Rheumatoid nodules occur in 20% of patients with RA. These nodules are seen most commonly on the extensor surfaces of the elbows, forearms, and hands but also may be seen on the feet and at other pressure points. They also may develop in the lung or pleural lining of the lung and, rarely, in the meninges. Rheumatoid nodules usually are asymptomatic and do not require any special intervention. Nodules are observed more commonly in patients with erosive disease.[17]

Vasculitis

Vasculitis usually is seen in patients with long-standing RA. Vasculitis may result in a wide variety of clinical presentations. Invasion of blood vessel walls by inflammatory cells results in an obliteration of the vessel, producing infarction of tissue distal to the area of involvement. Most commonly, small-vessel vasculitis produces infarcts near the ends of the fingers or toes, especially around the nail beds. These infarcts are usually of little consequence.

Vasculitis also may cause the breakdown of skin, especially in the lower extremities, producing ulcers that may be indistinguishable in appearance from stasis ulcers. However, these ulcers do not heal with the usual modes of treatment used for stasis ulcers.

Involvement of larger vessels with vasculitis can result in life-threatening complications. Infarction of vessels supplying blood to nerves can cause irreversible motor deficits. Involvement of vessels supplying other organ systems can lead to visceral involvement and a polyarteritis nodosa-like illness. Aggressive treatment of the inflammatory process is necessary in these patients. Fortunately, the more serious vasculitic picture is seen rarely.

Pulmonary Complications

Rheumatoid arthritis may involve the pleura of the lung, which is often asymptomatic, although pleural effusions may result. Pulmonary fibrosis also may develop as a result of rheumatoid involvement; smoking appears to increase the risk of this complication. Rheumatoid nodules may develop in lung tissue and appear similar to neoplasms on chest radiographs. Interstitial pneumonitis and arteritis are rare, potentially life-threatening complications of RA.

Ocular Manifestations

Ocular manifestations include keratoconjunctivitis sicca and inflammation of the sclera, episclera, and cornea. Atrophy of the lacrimal duct may result in a decrease in tear formation, causing dry and itchy eyes, termed *keratoconjunctivitis sicca*. When this is observed in association with RA, it is referred to as *Sjögren's syndrome*. Artificial tears may be used to relieve symptoms. The salivary glands may also be involved in Sjögren's syndrome, resulting in dry mouth (xerostomia). Inflammation of the superficial layers of the sclera (episcleritis) is generally self-limiting. Involvement of deeper tissues (scleritis) usually results in a more serious, painful, and chronic inflammation. Rheumatoid nodules may develop on the sclera.

Cardiac Involvement

The heart is sometimes affected by RA. Rheumatoid arthritis is associated with an increased risk of cardiovascular mortality. This risk appears to be higher in those with more active inflammation and is reduced with treatment, particularly with methotrexate.[18,19] Pericarditis may occur, resulting in the accumulation of fluid. Although many patients show evidence of previous pericarditis at autopsy, the development of clinically evident pericarditis with tamponade is a rare complication. Cardiac conduction abnormalities and aortic valve incompetence, caused by aortic root dilation, may occur. Myocarditis is a rare complication of RA.

Felty's Syndrome

Rheumatoid arthritis in association with splenomegaly and neutropenia is known as *Felty's syndrome*. Thrombocytopenia also may be a manifestation of the syndrome. Patients with Felty's syndrome and severe leukopenia are more susceptible to infection. The decrease in granulocytes appears to be mediated by the immune system because splenectomy does not result in improvement of the patient.[17]

Other Complications

Lymphadenopathy may occur in patients with RA, particularly in nodes proximal to more actively involved joints. Renal involvement is rare but can be associated with treatment, including nonsteroidal antiinflammatory drugs (NSAIDs), gold salts, and penicillamine. Amyloidosis is a rare complication of longstanding RA. It appears to be more common in Europe than in the United States.

LABORATORY FINDINGS

Hematologic tests often reveal a mild to moderate anemia with normocytic, normochromic indices. The hematocrit may fall as low as 30%. The anemia is usually inversely related to inflammatory disease activity and is referred to as an *anemia of chronic disease*. This type of anemia does not respond to iron therapy and can present a diagnostic dilemma because NSAIDs may induce gastritis and chronic blood loss, leading to iron-deficiency anemia. Laboratory tests useful in differentiating these anemias include stool guaiac (or other stool tests for occult blood), serum iron-to-iron-binding capacity ratio (decreased in iron deficiency), ferritin (decreased in iron deficiency), and mean corpuscular volume (more likely to be decreased in iron deficiency). Other causes of anemia also must be considered in the differential diagnosis (see Chapters 109 and 111).

Thrombocytosis is another common hematologic finding with active RA. Platelet counts rise and fall in direct correlation with disease activity in many patients. Thrombocytopenia may result from toxicity of immunosuppressive therapy. Thrombocytopenia also may be observed in Felty's syndrome or vasculitis.

Although leukopenia is associated with Felty's syndrome, it also may result from toxicity of methotrexate, gold, sulfasalazine, penicillamine, and immunosuppressive drugs. Leukocytosis is seen commonly as a result of corticosteroid treatment.

The erythrocyte sedimentation rate is usually elevated in patients with RA and other inflammatory diseases. This test is very nonspecific, and although the erythrocyte sedimentation rate usually falls as patients respond to therapy, there is a large variability among patients in response to treatment. C-reactive protein is another nonspecific marker for inflammatory arthritis when it is elevated. This protein is produced by the liver in response to certain cytokines.

Rheumatoid factor is present in 60% to 70% of patients with RA. The usual laboratory test for rheumatoid factor is an antibody specific for immunoglobulin (Ig)M rheumatoid factor. Patients with RA and a negative test for rheumatoid factor may have IgG or IgA rheumatoid factors, but tests for these are not routinely available. Rheumatoid factor tests may be reported positive at a specific serum dilution. Serum is diluted to a standard series of dilutions; the greatest dilution that yields a positive test result will be reported (e.g., rheumatoid factor positive at 1:640). Some laboratories quantify rheumatoid factor rather than using titers. Higher dilutional titers or serum concentrations of rheumatoid factors usually indicate a more severe disease, but like the erythrocyte sedimentation rate, the large interpatient variability makes this test unreliable as a means of assessing patient progress. Rheumatoid factor may be positive in patients without RA (Table 100–1).

Anticyclic citrullinated peptide antibody has similar sensitivity for RA, being found in 50% to 85% of patients with the disease, but is

TABLE 100-1 Diseases Associated with a Positive Rheumatoid Factor

Rheumatic diseases

Leprosy
Other causes
Aging
Interstitial pulmonary fibrosis
Cirrhosis of the liver
Chronic active hepatitis
Sarcoidosis

more specific (90%–95%) and is detectable very early in the disease. Many rheumatologists will do both tests in evaluating new patients.

Antinuclear antibodies are detected in 25% of patients with RA. These antibodies usually have a diffuse pattern of immunofluorescence. Tests for antibodies to double-stranded DNA (usually positive in systemic lupus erythematosus) are negative. Serum complement is usually normal, although complement concentrations of joint fluid often are depressed from consumption secondary to the inflammatory process. In patients with vasculitis, serum complement concentrations may be low.[20,21]

Synovial fluid usually is turbid because of the large number of leukocytes in inflammatory fluid. White cell counts of 5,000 to 50,000/mm^3 (5×10^9 to 50×10^9/L) are not uncommon in inflamed joints. The fluid is usually less viscous than that in normal joints or in fluid associated with osteoarthritis. Glucose concentrations of joint fluid are normal or low compared with those in serum drawn at the same time as synovial aspirates. The decrease is not as profound as the decrease associated with joint infection or systemic lupus erythematosus.

Early radiographic manifestations of RA include soft-tissue swelling and osteoporosis near the joint (periarticular osteoporosis). Joint space narrowing occurs as a result of cartilage degradation. Erosions tend to occur later in the course of the disease and usually are seen first in the metacarpophalangeal and proximal interphalangeal joints of the hands and the metatarsophalangeal joints of the feet. Periodic joint radiographs are a useful way of evaluating disease progression.

Seronegative Inflammatory Arthritis

Although RA may have a negative rheumatoid factor titer, a number of other systemic inflammatory arthritic conditions exist including psoriatic arthritis, reactive arthritis, ankylosing spondylitis, and arthritis associated with inflammatory bowel disease. These conditions often tend to be less aggressive than what is typically seen with RA. Detailed discussion about these conditions is beyond the scope of this chapter, but further information may be found elsewhere.[2] Management principles are similar to those for RA.

TREATMENT

Rheumatoid Arthritis

DESIRED OUTCOME

2 The primary objective is to improve or maintain functional status, thereby improving quality of life. Treatment of RA is a multifaceted approach that includes pharmacologic and nonpharmacologic therapies. Recent emphasis has been placed on aggressive treatment early in the disease course. The ultimate goal is to achieve complete disease remission, although this goal may not be possible to achieve in some patients. Additional goals of treatment include controlling disease activity and joint pain, maintaining the ability to function in daily activities or work, improving the quality of life, and slowing destructive joint changes.

NONPHARMACOLOGIC THERAPY

3 Rest, occupational therapy, physical therapy, use of assistive devices, weight reduction, and surgery are the most useful types of nonpharmacologic therapy used in patients with RA. Rest is an essential component of a nonpharmacologic treatment plan. It relieves stress on inflamed joints and prevents further joint destruction. Rest also aids in alleviation of pain. Too much rest and immobility, however, may lead to decreased range of motion and, ultimately, muscle atrophy, and contractures.

Occupational and physical therapy can provide the patient with skills and exercises necessary to increase or maintain mobility. These disciplines also may provide patients with supportive and adaptive devices such as canes, walkers, and splints.

Other nonpharmacologic therapeutic options include weight loss and surgery. Weight reduction helps to alleviate inflamed joint stress. This should be instituted and monitored with close supervision of a healthcare professional. Tenosynovectomy, tendon repair, and joint replacements are surgical options for patients with RA. Such management is reserved for patients with severe disease.[22–24]

PHARMACOLOGIC THERAPY

4 5 A disease-modifying antirheumatic drug (DMARD) should be started within the first 3 months of symptom onset (Fig. 100–5).[22] Early introduction of DMARDs results in a more favorable outcome.[25–30] NSAIDs and/or corticosteroids may be used for symptomatic relief if needed. They provide relatively rapid improvement in symptoms compared with DMARDs, which may take weeks to months before benefit is seen; however, NSAIDs have no impact on disease progression and the long-term complication risk of corticosteroids make them less desirable.[28]

Early treatment with DMARDs can reduce mortality. Patients with RA have increased mortality compared to people without the disease. In one trial, methotrexate reduced risk of mortality.[18] Early treatment with DMARDs in patients followed for up to 10 years had mortality rates similar to patients without the disease.[31]

DMARDs including biologic agents should be used in all patients except those with limited disease. DMARDs commonly used include methotrexate, hydroxychloroquine, sulfasalazine, and leflunomide. The biologic agents that have disease-modifying activity include the anti-TNF drugs (etanercept, infliximab, adalimumab, certolizumab, golimumab), the costimulation modulator abatacept, and rituximab, which depletes peripheral B cells. Less frequently used are the IL-1 receptor antagonist anakinra, azathioprine, D-penicillamine, gold (including auranofin), minocycline, cyclosporine, and cyclophosphamide. This is due to either less efficacy, high toxicity, or both. The order in which the first-line agents are used is not clearly defined, although methotrexate is often chosen because long-term data suggests superior outcomes with methotrexate than with other DMARDs and a lower cost than biologic agents. Leflunomide appears to have similar long-term efficacy as that of methotrexate.[32]

The biologics have proven effective for patients who fail treatment with other DMARDs. Infliximab should be given in combination with methotrexate to prevent development of antibodies that may reduce drug efficacy or induce allergic reactions. Methotrexate

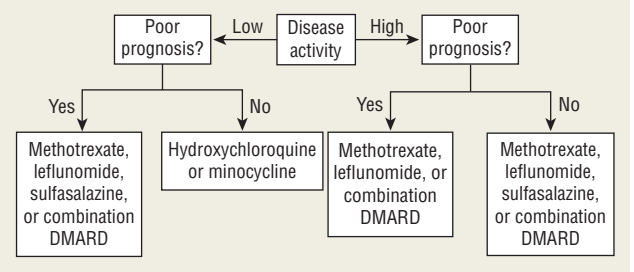

FIGURE 100-5. Algorithm for treatment of rheumatoid arthritis using non-biologic DMARDs. Poor prognosis is defined as limitation in function, extra-articular findings (rheumatoid nodules, vasculitis, Felty syndrome, Sjogren syndrome, rheumatoid lung findings, erosions on radiograph). (DMARD, disease-modifying antirheumatic drug; MTX, methotrexate; NSAID, nonsteroidal antiinflammatory drug.)

in combination with other biologics is more effective than biologic monotherapy and the combination is frequently used.[23]

6 Combination therapy with two or more DMARDs may be effective when single-DMARD treatment is unsuccessful.[28,33–39] One study suggests that the initial combination therapy with either methotrexate, sulfasalazine plus prednisone, or infliximab plus methotrexate were superior to more conventional sequential monotherapy or step-up combinations of DMARDs in early rheumatoid arthritis.[35] For patients with moderate to high disease activity, the American College of Rheumatology recommendations for nonbiologic and biologic DMARDs are dual DMARD combinations of methotrexate plus hydroxychloroquine, methotrexate plus leflunomide, or methotrexate plus sulfasalazine. They also recommend the triple combination of sulfasalazine, hydroxychloroquine, and methotrexate.[23]

Corticosteroids can be used in various ways. They are valuable in controlling symptoms before the onset of action of DMARDs. A burst of corticosteroids can be used in acute flares. Continuous low doses may be adjuncts when DMARDs do not provide adequate disease control. Corticosteroids may be injected into joints and soft tissues to control local inflammation. Corticosteroids seldom should be used as monotherapy. There are data to suggest they have disease-modifying activity;[35,36,40] however, it is preferable to avoid chronic use when possible to avoid long-term complications. NSAIDs and DMARDs have steroid-sparing properties that permit reductions of corticosteroid doses.

As immunosuppression may reduce the ability to mount an antibody response, the need for immunizations should be assessed, and these should be administered if needed before nonbiologic or biologic DMARDs are started.[23] Postvaccination antibody titers seem to be only minimally affected by conventional DMARDs and TNF antagonists. Rituximab and abatacept seem to reduce the ability to develop antibodies after vaccination. Live vaccines are not recommended for patients taking biologic DMARDs.[41]

The American College of Rheumatology published recommendations for use of nonbiologic and biologic DMARDs in 2008. These recommendations are not intended to be prescriptive but provide guidance for treatment choice. Recommendations are given based on disease duration, degree of disease activity, and likely prognosis. The recommendations take into account barriers to treatment, including cost and insurance restrictions, by suggesting treatment options with and without expensive biologic treatments. Simplified algorithms summarizing these treatment recommendations are provided in Figures 100–5 and 100–6. For more details, see the published recommendation.[23]

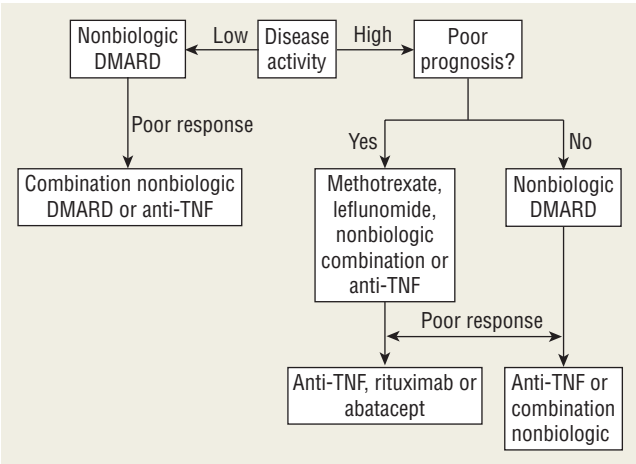

FIGURE 100-6. Algorithm for treatment of rheumatoid arthritis using biologic agents.

7 Tables 100–2, 100–3, and 100–4 provide monitoring parameters and dosing guidelines for DMARDs and NSAIDs used in rheumatoid arthritis.

Nonsteroidal Antiinflammatory Drugs

NSAIDs should seldom be used as monotherapy for rheumatoid arthritis because they do not alter the course of the disease; instead, they should be viewed as adjuncts to DMARD treatment. NSAIDs possess both analgesic and antiinflammatory properties and reduce stiffness associated with RA. NSAIDs mainly inhibit prostaglandin synthesis, which is only a small portion of the inflammatory cascade. For details on these agents see Chapter 101, Osteoarthritis.

Methotrexate

Methotrexate is now considered the nonbiologic DMARD of choice by many rheumatologists for treating RA. In psoriatic arthritis it not only treats the joint symptoms but also improves the skin disease for most patients. Methotrexate is contraindicated in pregnant and nursing women. It is also contraindicated in patients with chronic liver disease, immunodeficiency, pleural or peritoneal effusions, leukopenia, thrombocytopenia, preexisting blood disorders, and a creatinine clearance of less than 40 mL/min.

Absorption of methotrexate is variable and averages approximately 70% of an oral dose. Methotrexate is 35% to 50% bound to albumin; it may be displaced by highly protein-bound drugs such as NSAIDs, but the clinical importance of this interaction in the relatively low doses of methotrexate used in RA is unknown. Methotrexate is extensively metabolized intracellularly to polyglutamated derivatives. It is excreted by the kidney, 80% unchanged, by glomerular filtration and active transport. Some methotrexate may be reabsorbed, but this transport process may be saturated even with low doses, resulting in increased renal clearance.

Methotrexate inhibits cytokine production, inhibits purine biosynthesis, and may stimulate release of adenosine, all of which may lead to its antiinflammatory properties. The drug has a fairly rapid onset of action; results may be seen as early as 2 to 3 weeks after starting therapy. Some 45% to 67% of patients remain on methotrexate therapy in studies ranging from 5 to 7 years.[42,43] Methotrexate may be given intramuscularly, subcutaneously, or orally. Doses greater than 15 mg per week generally are given parenterally because of decreased oral bioavailability of larger doses.

The toxicities of methotrexate therapy are mainly gastrointestinal, hematologic, pulmonary, and hepatic. Stomatitis occurs in 3% to 10% of patients and may be painful or painless. Diarrhea, nausea, and vomiting may occur in up to 10% of patients. The most common hematologic toxicity is thrombocytopenia in 1% to 3% of patients. Leukopenia also may occur, but in a smaller number of patients. Although pulmonary fibrosis and pneumonitis can be severe adverse effects, they are rare.

Elevated liver enzymes may occur in up to 15% of patients; cirrhosis is rare. Liver function tests, aspartate aminotransferase or alanine aminotransferase, should be performed periodically. Methotrexate should be discontinued if these test values show sustained results greater than twice the upper limits of normal. An albumin blood level also should be checked periodically as a sign of liver toxicity because some patients may not have liver inflammation manifested by aspartate aminotransferase or alanine aminotransferase elevation. Liver biopsy is now recommended before beginning methotrexate therapy only for patients with a history of excessive alcohol use, ongoing hepatitis B or C infection, or recurring elevation of aspartate aminotransferase. Biopsies dur-

TABLE 100-2 Usual Doses and Monitoring Parameters for Antirheumatic Drugs

Drug	Usual Dose	Initial	Maintenance
Nonsteroidal anti-inflammatory drugs	See Table 101–2 in Chap. 101	S_{cr} or BUN, CBC q 2–4 wk p starting therapy × 1–2 mo salicylates: serum salicylate levels if therapeutic dose and no response	Same as initial plus stool guaiac q 6–12 mo
Methotrexate	Oral or IM: 7.5–15 mg q wk	Baseline: AST, ALT, alk phos, alb, t. bili, hep B & C studies, CBC w/plt, S_{cr}	CBC w/plt, AST, alb q 1–2 mo
Leflunomide	Oral: 100 mg daily for 3 days then 10–20 mg daily or 10–20 mg daily without loading dose	Baseline: ALT, CBC with platelets	CBC with platelets and ALT monthly initially and then every 6–8 wk
Hydroxychloroquine	Oral: 200–300 mg bid, after 1–2 mo may to 200 mg bid or daily	Baseline: color fundus photography and automated central perimetric analysis	Ophthalmoscopy q 9–12 mo and Amsler grid at home q 2 wk
Sulfasalazine	Oral: 500 mg bid, then ? to 1 g bid max	Baseline: CBC w/plt, then q week × 1 month	Same as initial–q 1–2 mo
Minocycline	Oral 100–200 mg daily	None	None
Etanercept	50 mg SC weekly	Tuberculin skin test	None
Infliximab	3 mg/kg IV at 0, 2, 6 weeks then q 8 weeks	Tuberculin skin test	None
Adalimumab	40 mg SC q 2 weeks	Tuberculin skin test	None
Rituximab	1,000 mg twice, 2 weeks apart	None	None
Abatacept	<60 kg (<132 lbs)–500 mg 60–100 kg (132–220 lbs)–750 mg >100 kg (>220 lbs)–1,000 mg	None	None
Tocilizumab	4–8 mg/kg q 4 weeks	AST/ALT, CBC w/plt, lipids	AST/ALT, CBC w/plt, lipids q 4–8 weeks
Anakinra	100 mg SC daily	Neutrophil count	Neutrophil count monthly for 3 months then quarterly up to 1 year
Auranofin	Oral: 3 mg daily to bid	Baseline: UA, CBC w/plt	Same as initial–q 1–2 mo
Gold thiomalate	IM: 10 mg test dose, then weekly dosing 25–50 mg, after response may ↑ dosing interval	Baseline & until stable: UA, CBC w/plt preinjection	Same as initial–every other dose
Azathioprine	Oral: 50–150 mg daily	CBC w/plt, AST q 2 weeks × 1–2 months	Same as initial–q 1–2 mo
D-Penicillamine	Oral: 125–250 mg daily, may ↑ by 125–250 mg q 1–2 months, max 750 mg daily	Baseline: UA, CBC w/plt, then q week × 1 month	Same as initial–q 1–2 mo, but q 2 wk if dose change
Cyclophosphamide	Oral: 1–2 mg/kg/day	UA, CBC w/plt q week × 1 month	Same as initial–q 2–4 wk
Cyclosporine	Oral: 2.5 mg/kg/day	S_{cr}, blood pressure q month	Same as initial
Corticosteroids	Oral, IV, IM, IA, and soft-tissue injections: variable	Glucose, blood pressure q 3–6 months	Same as initial

alb, albumin; alk phos, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count; hep, hepatitis; IA, intraarticular; IM, intramuscular; IV, intravenous; p, after; plt, platelet; q, every; S_{cr}, serum creatinine; t. bili, total bilirubin; UA, urinalysis.

ing methotrexate therapy are recommended only for patients who develop consistently abnormal liver function tests.[22]

Because the drug is teratogenic, patients should use contraception to avoid pregnancy and discontinue the drug if conception is planned.

Because it is a folic acid antagonist, methotrexate can induce a folic acid deficiency. This deficiency is thought to be partly responsible for methotrexate toxicity, and supplementation with folic acid does alleviate some adverse effects. Addition of folic acid to a methotrexate regimen for RA does not compromise drug efficacy.[22,23,44–47]

TABLE 100-3 Clinical Monitoring of Drug Therapy in Rheumatoid Arthritis

Drug	Toxicities Requiring Monitoring	Symptoms to Inquire About[a]
NSAIDs and salicylates	GI ulceration and bleeding, renal damage	Blood in stool, black stool, dyspepsia, nausea/vomiting, weakness, dizziness, abdominal pain, edema, weight gain, SOBC
Corticosteroids	Hypertension, hyperglycemia, osteoporosis[b]	Blood pressure if available, polyuria, polydipsia, edema, SOB, visual changes, weight gain, headaches, broken bones or bone pain
Azathioprine	Myelosuppression, hepatotoxicity, lymphoproliferative disorders	Symptoms of myelosuppression (extreme fatigue, easy bleeding or bruising, infection), jaundice
Gold (intramuscular or oral)	Myelosuppression, proteinuria, rash, stomatitis	Symptoms of myelosuppression, edema, rash, oral ulcers, diarrhea
Hydroxychloroquine	Macular damage, rash, diarrhea	Visual changes including a decrease in night or peripheral vision, rash, diarrhea
Methotrexate	Myelosuppression, hepatic fibrosis, cirrhosis, pulmonary infiltrates or fibrosis, stomatitis, rash	Symptoms of myelosuppression, SOB, nausea/vomiting, lymph node swelling, coughing, mouth sores, diarrhea, jaundice
Leflunomide	Hepatitis, GI distress, alopecia	Nausea/vomiting, gastritis, diarrhea, hair loss, jaundice
Penicillamine	Myelosuppression, proteinuria, stomatitis, rash, dysgeusia	Symptoms of myelosuppression, edema, rash, diarrhea, altered taste perception, oral ulcers
Sulfasalazine	Melosuppression, rash	Symptoms of myelosuppression, photosensitivity, rash, nausea/vomiting
Etanercept, adalimumab, golimumab, certolizumab, tocilizumab, anakinra	Local injection-site reactions, infection	Symptoms of infection
Infliximab, rituximab, abatacept	Immune reactions, infection	Postinfusion reactions, symptoms of infection

GI, gastrointestinal; NSAIDs, nonsteroidal antiinflammatory drugs; SOB, shortness of breath.

[a]Altered immune function increases infection which should be considered particularly in those patients taking azathioprine, methotrexate, and corticosteroids or other drugs as a symptom of myelosuppression.

[b]Osteoporosis is unlikely to manifest itself early in treatment, but all patients should be taking appropriate steps to prevent bone loss.

TABLE 100-4 Dosage Regimens for Nonsteroidal Antiinflammatory Drugs

	Recommended Antiinflammatory Total Daily Dosage		
Drug	***Adult***	***Children***	**Dosing Schedule**
Aspirin	2.6–5.2 g	60–100 mg/kg	Four times daily
Celecoxib	200–400 mg	–	Daily to twice daily
Diclofenac	150–200 mg		Three times per day to 4 times daily Extended release twice daily
Diflunisal	0.5–1.5 g	–	Twice daily
Etodolac	0.2–1.2 g (max. 20 mg/kg)	–	Twice daily to 4 times daily
Fenoprofen	0.9–3.0 g	–	Four times daily
Flurbiprofen	200–300 mg	–	Twice daily to 4 times daily
Ibuprofen	1.2–3.2 g	20–40 mg/kg	Three times per day to 4 times daily
Indomethacin	50–200 mg	2–4 mg/kg (max. 200 mg)	Twice daily to 4 times daily Extended release daily
Meclofenamate	200–400 mg	–	Three times per day to 4 times per day
Meloxicam	7.5–15 mg	–	Daily
Nabumetone	1–2 g	–	Daily to twice daily
Naproxen	0.5–1.0 g	10 mg/kg	Twice daily Extended release–daily
Naproxen sodium	0.55–1.1 g	–	Twice daily
Nonacetylated salicylates	1.2–4.8 g	–	Twice daily to 6 times per day
Oxaprozin	0.6–1.8 g (max. 26 mg/kg)	–	Daily to 3 times a day
Piroxicam	10–20 mg	–	Daily
Sulindac	300–400 mg	–	Twice daily
Tolmetin	0.6–1.8 g	15–30 mg/kg	Twice daily to 4 times daily

Leflunomide

Leflunomide is a DMARD that inhibits pyrimidine synthesis, leading to a decrease in lymphocyte proliferation and modulation of inflammation. It is given as a loading dose of 100 mg daily for 3 days, followed by a maintenance dose of 20 mg daily. Lower doses may be used if patients have gastrointestinal intolerance, complain of hair loss, or have other signs of dose-related toxicity. The loading dose allows the patient to achieve a more rapid therapeutic response, usually within the first month. The long elimination half-life of the drug (14–16 days) would require the patient to take the drug for several months to achieve steady state without a loading dose. Some rheumatologists prefer to begin with maintenance dosing as the loading dose may put the patient at increased risk for toxicity.

Leflunomide has efficacy similar to methotrexate for treating RA. The drug may cause liver toxicity and is contraindicated in patients with preexisting liver disease. Patients taking the drug should have alanine aminotransferase monitored monthly initially and periodically thereafter as long as they continue treatment. Leflunomide may cause bone marrow toxicity and complete blood count with platelets is recommended monthly for 6 months and then every 6 to 8 weeks thereafter.

The drug is teratogenic, and appropriate contraceptive measures are recommended to avoid pregnancy for all sexually active male and female patients who are taking leflunomide. If conception is desired, leflunomide must be discontinued. Because leflunomide undergoes enterohepatic circulation, the drug takes many months to drop to a plasma concentration considered safe during pregnancy (<0.02 μg/mL [<0.02 mg/L; 74 nmol/L]). Cholestyramine may be used to rapidly clear the drug from plasma. In addition to pregnancy, cholestyramine use may be warranted to rapidly clear the drug in the event of severe toxicity.[32,48–51]

Hydroxychloroquine

The pharmacokinetics of hydroxychloroquine are poorly understood. It is well absorbed orally and widely distributed to body tissues. Hydroxychloroquine is partially metabolized in the liver and is excreted by the kidney. The onset of action of hydroxychloroquine may be delayed up to 6 weeks, but the drug is considered a therapeutic failure only when 6 months of therapy without a response has elapsed.

The main advantage of hydroxychloroquine is the lack of myelosuppressive, hepatic, and renal toxicities that may be seen with other DMARDs, which simplifies monitoring. Short-term toxicities of hydroxychloroquine include gastrointestinal effects such as nausea, vomiting, and diarrhea, which can be managed by taking doses with food. Ocular toxicity includes accommodation defects, benign corneal deposits, blurred vision, scotomas (small areas of decreased or absent vision in the visual field), and night blindness. Although the risk of true retinopathy with hydroxychloroquine approaches zero, preretinopathy may occur in 2.7% of patients. All patients must understand the importance of adhering to hydroxychloroquine monitoring guidelines, as delineated in Table 100–2. Any visual change must be reported immediately. Dermatologic toxicities include rash, alopecia, and increased skin pigmentation; neurologic adverse effects such as headache, vertigo, and insomnia usually are mild.[38,52,53]

Sulfasalazine

Sulfasalazine, a prodrug, is cleaved by bacteria in the colon into sulfapyridine and 5-aminosalicylic acid. It is believed that the sulfapyridine moiety is responsible for the agent's antirheumatic properties, although the exact mechanism of action is unknown. Once the colonic bacteria have cleaved sulfasalazine, sulfapyridine and 5-aminosalicylic acid are absorbed rapidly from the gastrointestinal tract. Sulfapyridine distributes rapidly throughout the body, but higher concentrations are found in certain tissues such as serous fluid, liver, and intestines. Both sulfasalazine and its metabolites are excreted in the urine. Antirheumatic effects should be seen in 2 months.

Use of sulfasalazine is often limited by its adverse effects. Gastrointestinal adverse effects such as nausea, vomiting, diarrhea, and anorexia are the most common. These can be minimized by initiating therapy with low doses and titrating gradually to higher doses, dividing the dose more evenly throughout the day, or using

enteric-coated preparations. Rash, urticaria, and serum sickness-like reactions can be managed with antihistamines and, if indicated, corticosteroids. If a hypersensitivity reaction occurs, therapy should be stopped immediately and another DMARD substituted. Sulfasalazine is associated with leukopenia, alopecia, stomatitis, and elevated hepatic enzymes. It also may cause the patient's urine and skin to turn a yellow-orange color, which is of no clinical consequence however; patients should be educated about this to avoid premature discontinuance.

Sulfasalazine's absorption can be decreased when antibiotics are used that destroy the colonic bacteria. Sulfasalazine also binds iron supplements in the gastrointestinal tract that can lead to a decreased absorption of sulfasalazine. The administration of these two agents should be separated temporally to avoid this interaction. Sulfasalazine can potentiate warfarin's effects by displacing it from protein-binding sites. Close monitoring of the patient's international normalized ratio is indicated.[54,55]

Minocycline

The tetracycline derivative minocycline has been suggested as a treatment alternative for patients with RA who have low disease activity and without features of poor prognosis. A meta-analysis of 10 clinical trials using tetracyclines for more than 3 months found mild reductions in tender and swollen joint counts and erythrocyte sedimentation rate but no effect on erosion progression; however, the number of patients and treatment duration in the 2 trials that looked at erosions were limited.[56]

The dose of minocycline in RA is 100–200 mg daily.[56]

Adverse effects are uncommon and were reported no more frequently than placebo control groups.[56]

Other Disease-Modifying Antirheumatic Drugs

Gold salts, azathioprine, D-penicillamine, cyclosporine, and cyclophosphamide have all been used to treat RA. Although these drugs can be effective and they may be of value in certain clinical settings, they are used less frequently today because of toxicity, lack of long-term benefit, or both. Tables 100–2 and 100–3 provide dosing information and toxicity information.

Biologic Agents

Biologic agents are genetically engineered protein molecules that block the proinflammatory cytokines TNF-α (infliximab, etanercept, adalimumab, golimumab, and certolizumab), IL-1 (anakinra), and IL-6 (tocilizumab), deplete peripheral B cells (rituximab), or bind to CD80/86 on T cells to prevent the costimulation needed to fully activate T cells (abatacept). These drugs may be effective when other DMARDs fail to achieve adequate responses but are considerably more expensive to use. Other than anakinra and tocilizumab, these agents have no toxicity that requires laboratory monitoring, but they do carry a small increased risk for infection. There is an increased incidence of tuberculosis in patients treated with these agents. Tuberculin skin testing is recommended prior to treatment with these drugs so that latent tuberculosis can be detected.[57–60] Patients with a history of significant tuberculosis exposure or recurrent infection may not be good candidates for these drugs. Those who develop infections while on biologic agents should at least temporarily discontinue them until the infection is cured. Live vaccines should not be given to patients taking biologic agents.

TNF-α Inhibitors

Congestive heart failure (CHF) is a relative contraindication for anti-TNF agents. Increased cardiac mortality has been seen in patients treated with infliximab and etanercept-associated heart failure exacerbations have been documented.[51,61–63] Patients with a history of uncompensated CHF or recent hospital admissions for CHF should not use anti–TNF-α therapy. Patients whose CHF worsens while taking anti–TNF-α therapy should discontinue the drug.

Anti–TNF-α therapy has been reported to induce a multiple sclerosis-like illness or exacerbate multiple sclerosis in patients with the disease. Patients with neurologic symptoms suggestive of multiple sclerosis should discontinue therapy. TNF inhibitors may predispose patients to increased cancer risk, especially lymphoproliferative cancer, as TNF plays a role in ridding the body of cancer cells. The U.S. Food and Drug Administration (FDA) added a black box warning to product labeling for anti-TNF drugs alerting prescribers of increased lymphoproliferative and other cancers in children and adolescents treated with these drugs.[64]

Etanercept Etanercept is a fusion protein consisting of two p75-soluble TNF receptors linked to an Fc fragment of human IgG_1. The drug binds to TNF, making it biologically inactive and preventing it from interacting with the cell-surface TNF receptors that would lead to cell activation.

The drug is given by subcutaneous injection, 50 mg once weekly or 25 mg twice weekly, usually through self-injections or administration by a caregiver. Aside from local injection-site reactions, adverse effects are rare. There are case reports of pancytopenia and neurologic demyelinating syndromes like multiple sclerosis associated with use of etanercept, but these are rare. No laboratory monitoring is required. Clinical trials have used etanercept in patients who failed DMARDs. Response was seen in 60% to 75% of patients. The drug has also been FDA approved for the treatment of juvenile rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and moderate to severe psoriasis. Clinical trials have shown that it slows erosive disease progression to a greater degree than oral methotrexate therapy.[65–70]

Infliximab Infliximab is a chimeric antibody combining portions of mouse and human IgG_1. An anti-TNF antibody was created by exposing mice to human TNF. The binding portion of that antibody was fused to a human constant-region IgG_1 to reduce the antigenicity of the foreign protein. This antibody, when injected in humans, binds to TNF and prevents its interaction with TNF receptors on inflammatory cells.

Infliximab is given by intravenous infusion at a dose of 3 mg/kg at 0, 2, and 6 weeks and then every 8 weeks. To prevent the formation of antibodies to this foreign protein, methotrexate should be given orally in doses typically used to treat RA for as long as the patient continues on infliximab. Antibodies develop in 7% to 15% of patients, which leads to a greater risk of infusion reactions and also may reduce the efficacy of the drug. Loss of response may be seen in patients with RA who have good initial response requiring increased doses or shorter intervals between doses to maintain response. Infusion reactions may occur in any patient treated with the drug. Both acute (within 24 hours of infusion) and delayed (24 hours to 14 days) reactions following infusion have been identified. An acute infusion reaction with symptoms including fever, chills, pruritus, and rash may occur during infusion or within 1 to 2 hours after giving the drug. Treatment includes slowing infusion rates and administering acetaminophen, diphenhydramine, or corticosteroids, depending on the severity of symptoms. Fortunately these reactions are rarely severe or anaphylactic in nature.[71] The drug may increase risk of infection. Autoantibodies and lupus-like syndrome also have been reported. In clinical trials, the combination of methotrexate plus infliximab halted progression of joint damage in patients and was superior to methotrexate monotherapy.[72–74] In addition to rheumatoid arthritis, infliximab

is indicated for the treatment of psoriatic arthritis and ankylosing spondylitis.[72,75]

Adalimumab Adalimumab is a human IgG_1 antibody to TNF. Because it has no foreign protein components, it is less antigenic than infliximab. The drug is provided as either premixed syringes or injection pens containing 40 mg, which is administered by subcutaneous injection every 14 days. It has similar response rates to those seen with the other TNF inhibitors. Local injection-site reactions were the most common adverse reactions noted in clinical trials. It has the same precautions regarding tuberculosis and other infections as the other biologics.[76–80]

Golimumab Golimumab is a human antibody to TNF-α. In addition to RA, this agent is also indicated for treatment of psoriatic arthritis and ankylosing spondylitis. The drug is available as an injection pen, through which doses of 50 mg is given monthly by subcutaneous injection. Precautions are similar to other TNF-α inhibitors.

Certolizumab Certolizumab is a humanized antibody specific for human TNF-α. For RA, dosing recommendations are for 400 mg (2 doses of 200 mg) given by subcutaneous injection at weeks 0, 2, and 4 followed by 200 mg every 2 weeks. Precautions and side effects are similar to other TNF-α inhibitors.

Abatacept Abatacept is a costimulation modulator approved for the treatment of RA in patients with moderate to severe disease who fail to achieve an adequate response from one or more DMARDs. By binding to CD80/CD86 receptors on antigen-presenting cells, abatacept inhibits interactions between the antigen-presenting cells and T cells, preventing the T cell from activating to promote the inflammatory process, which results in reductions in cytokines, T-cell proliferation, and other consequences of T-cell activation. Abatacept is a fusion protein made using the extracellular domain of human cytotoxic T-lymphocyte antigen 4 (the binding portion of the drug) and a fragment of the Fc domain of human IgG modified to prevent complement fixation. The drug is given by intravenous infusion based on patient weight (<60 kg [<132 lb]: 500 mg; 60–100 kg [132–220 lb]: 750 mg; >100 kg [>220 lb]: 1,000 mg) every 2 weeks for two doses after the initial dose and then every 4 weeks. The adverse effects include headache, nasopharyngitis, dizziness, cough, back pain, hypertension, dyspepsia, urinary tract infection, rash, and extremity pain reported more frequently than placebo in clinical trials. Infusion reactions were 50% more likely with abatacept than with placebo and there was a slightly higher rate of serious infections with active treatment.[81–83] In patients who failed to achieve adequate responses with TNF-α inhibitors, half had a clinical response to abatacept.[84] Live vaccines should not be given to patients during and for 3 months after the completion of abatacept therapy.[84]

Rituximab Rituximab is a monoclonal chimeric antibody consisting of mostly human protein with the antigen-binding region derived from a mouse antibody to CD20 protein found on the cell surface of mature B lymphocytes. The binding of rituximab to B cells results in nearly complete depletion of peripheral B cells, with a gradual recovery over several months. The prolonged effect on B cells results in a duration of action that allows for intermittent therapy which varies based on reactivation of arthritis symptoms. Rituximab is useful in patients who failed methotrexate or TNF inhibitors.[85–89] Two infusions of 1,000 mg are given 2 weeks apart. Methylprednisolone 100 mg should be given 30 minutes prior to rituximab to reduce the incidence and severity of infusion reactions. Acetaminophen and antihistamines may also be of benefit in patients who have a history of reactions. Methotrexate should be given concurrently in the usual doses used for RA, as the combination has proved to provide the best therapeutic outcomes. Duration of benefit is variable after a course of rituximab and patients will need retreatment with reactivation of their disease. The drug is currently FDA approved for TNF inhibitor treatment failures. Live vaccines should not be given to patients given rituximab.

Tocilizumab IL-6 is a major cytokine believed to have a role in promoting inflammation in RA. Tocilizumab attaches to IL-6 receptors, which prevents the cytokine from interacting with cells. In clinical trials, 4 to 8 mg/kg was given intravenously every 4 weeks. It has been used as monotherapy or in combination with methotrexate. Infusion reactions and increased infection risk have been reported. Additionally, increased plasma lipids have been reported in tocilizumab-treated patients.

Anakinra Anakinra is a naturally occurring IL-1 receptor antagonist. Results of clinical trials suggest it to be less effective than other biologic DMARDs.[90] The American College of Rheumatology did not include anakinra in their RA treatment recommendations due to limited use of this drug, but some patients could benefit from treatment with this drug.[23]

Treatment Strategies for Patients with Suboptimal Response to Biologics

TNF-α antagonists are generally the first biologic agents chosen for use in patients with RA. Approximately 30% of patients discontinue treatment with these drugs because of lack of efficacy or adverse effects.

In such situations, addition of a nonbiologic DMARD may be beneficial if the patient is not already taking one. Dose escalation or decreased interval between infusions may be useful for those patients taking infliximab. Higher doses of other TNF-α inhibitors have not been demonstrated to be effective. Choosing an alternative TNF-α inhibitor may be beneficial for some patients. Treatment with rituximab or abatacept may also prove to be effective in TNF-α treatment failures. Combination biologic DMARD therapy is not recommended because of the increased risk for infection.[91]

Corticosteroids

Corticosteroids are used in RA for their antiinflammatory and immunosuppressive properties. They interfere with antigen presentation to T lymphocytes, inhibit prostaglandin and leukotriene synthesis, and inhibit neutrophil and monocyte superoxide radical generation. Corticosteroids also impair cell migration and cause redistribution of monocytes, lymphocytes, and neutrophils, thus blunting the inflammatory and autoimmune responses.

Oral corticosteroids are absorbed rapidly and completely from the gastrointestinal tract. They are metabolized and inactivated primarily by the liver and excreted in the urine. The elimination half-life of most corticosteroids is sufficiently long that once-daily dosing is possible.

Oral corticosteroids can be used in several ways. They can be used in bridging therapy, continuous low-dose therapy, and short-term, high-dose bursts to control flares. Oral steroids (e.g., prednisone, methylprednisolone) can be used to control pain and synovitis while DMARDs are taking effect. This is termed *bridging therapy* and is often used in patients with debilitating symptoms when DMARD therapy is initiated. Patients with difficult-to-control disease may be placed on low-dose, long-term corticosteroid therapy to control their symptoms. Prednisone doses below 7.5 mg daily are well tolerated but are not devoid of the long-term adverse effects associated with corticosteroids. The lowest dose of corticosteroid that controls symptoms should be used to reduce adverse effects. Alternate-day

dosing of low-dose oral corticosteroids usually is ineffective in RA; symptoms usually flare on days without medication. High-dose corticosteroid bursts often are used to suppress disease flares. High doses are sustained for several days until symptoms are controlled, followed by a taper to the lowest effective dose.

Corticosteroids also may be delivered by injection. The intramuscular route may be preferable in patients with adherence problems for short-term therapy. Long-acting depot forms of corticosteroids include triamcinolone acetonide, triamcinolone hexacetonide, and methylprednisolone acetate. This provides the patient with 2 to 6 weeks of symptomatic control. The depot effect provides a physiologic taper, avoiding withdrawal reaction associated with hypothalamic–pituitary axis suppression. Intravenous corticosteroids may be used to provide the patient with large amounts of drug during a steroid burst to control severe symptoms. Intraarticular injections of depot forms of corticosteroids can be useful in treating synovitis and pain when a small number of joints are affected. The onset and duration of symptomatic relief are similar to those of intramuscular injection. The intraarticular route often is preferred because it is associated with the fewest number of systemic adverse effects. If efficacious, intraarticular injections may be repeated every 3 months. No one joint should be injected more than 2 to 3 times per year because of the risk of accelerated joint destruction and atrophy of tendons. Soft tissues such as tendons and bursae also may be injected. This may help control the pain and inflammation associated with these structures. The onset and duration of symptomatic relief are similar to those of intramuscular and intraarticular injections.

The major limitation to the long-term use of corticosteroids is adverse effects. They include hypothalamic-pituitary–adrenal suppression, Cushing's syndrome, osteoporosis, myopathies, glaucoma, cataracts, gastritis, hypertension, hirsutism, electrolyte imbalances, glucose intolerance, skin atrophy, and increased susceptibility to infections. To minimize these effects, use the lowest effective corticosteroid dose and limit the duration of use. Prednisolone 7.5 mg daily results in an average of 9.5% loss of bone density from the spine. Corticosteroids double the risk for osteoporosis in patients.[92] Patients on long-term therapy should be given calcium and vitamin D to minimize bone loss. Alendronate is effective in preventing bone loss in corticosteroid-treated patients and should be considered prophylactically for patients when long-term corticosteroid therapy is anticipated, particularly for patients who are at high risk of bone loss (e.g., postmenopausal women, elderly).[93–96] There is no evidence that corticosteroids alone increase the risk of gastrointestinal ulcerations, although they often have been implicated. Consequently, gastrointestinal protective measures usually are not indicated.[97–99]

PHARMACOECONOMIC CONSIDERATIONS

The total cost of treating a patient with RA is estimated to be between $11,500 and $17,000 annually (2008 dollars). Of this, drugs account for roughly 10% of the total, excluding monitoring costs. These costs are approximately three times the cost of medical care for patients of similar age and gender without RA. However, if biologic agents are used, the cost of this drug therapy alone may be $12,000 or more annually. The costs must be balanced against the high cost of disability on earning potential in these patients. Men with RA have average annual wages 50% lower than those of men of similar age without RA. In women with the disease, average annual wages are only 25% of the wages of those women without the disease. The costs of disability make treatment worth the price if disability can be prevented or delayed and patients can continue to function as productive members of society.[100]

CLINICAL CONTROVERSIES

1. The order of DMARD or biologic agent choice is not clearly defined. No direct comparative studies exist for biologics to guide in the determination of optimal treatment order.
2. Should combination DMARD be tried before biologic agents?
3. Even the best therapy available today does not completely eliminate all signs and symptoms of disease for most patients. How much treatment is enough?
4. Some patients show evidence of disease progression in spite of apparent control of clinical symptoms. How can these patients be identified and treatment course changed before progression occurs?

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of therapeutic outcomes is based primarily on improvements of clinical signs and symptoms of RA. Clinical signs of improvement include a reduction in joint swelling, decreased warmth over actively involved joints, and decreased tenderness to joint palpation. Improvement in RA symptoms includes reduction in perceived joint pain and morning stiffness, longer time to onset of afternoon fatigue, and improvement in ability to perform activities of daily living. Improvement of activities of daily living may be assessed objectively using a Health Assessment Questionnaire score. Joint radiographs may be of some benefit in assessing the progression of the disease and should show little or no evidence of disease progression if treatment is effective.

Laboratory monitoring is of little value in monitoring individual patient response to therapy. Tables 100–2 and 100–3 provide monitoring of drug toxicity information. Routine monitoring of patients is essential to the safe use of these drugs. In addition, patients should be questioned about symptoms of the adverse effects outlined in the drug section of this chapter.

CONCLUSIONS

Rheumatoid arthritis is the most common inflammatory arthritis, affecting approximately 1% of the population. The disease is characterized by symmetrical swelling and stiffness of the involved joints. The stiffness is usually more prominent in the morning. Extraarticular features of RA include rheumatoid nodules, vasculitis, and ocular, cardiac, and pulmonary complications. The course of the disease is highly variable. Treatment is aimed at relieving pain and inflammation and maintaining and preserving joint function. Nondrug therapy, including exercise and adequate rest periods, should also be used early in the course of treatment. Early use of a DMARD or biologic agent results in better patient outcomes. Methotrexate, sulfasalazine, and hydroxychloroquine are often considered for initial therapy. Biologics have also been shown to be effective in these patients but may be considered second choice because of cost considerations; however, they are effective in patients who fail to achieve adequate response from nonbiologic DMARDs. Combination DMARDs or biologics may be considered in those who fail adequate trials of single-agent therapy. Corticosteroids and NSAIDs may be useful adjuncts for treatment, but because of adverse effects and limited impact on long-term outcomes, they should not be considered as sole treatment for most patients.

ABBREVIATIONS

CHF: congestive heart failure

DMARD: disease-modifying antirheumatic drug

HLA: human lymphocyte antigen

Ig: immunoglobulin

IL: interleukin

NSAID: nonsteroidal antiinflammatory drug

RA: rheumatoid arthritis

TNF-α: tumor necrosis factor α

CHAPTER 101

Osteoarthritis

LUCINDA M. BUYS AND MARY ELIZABETH ELLIOTT

KEY CONCEPTS

1. Millions of Americans have osteoarthritis (OA). OA prevalence increases with age; women more commonly affected than men.
2. Contributors to OA are systemic (e.g., age, gender, genetics, hormonal status, obesity, and occupational or recreational activity) and/or local (e.g., injury, overloading of joints, muscle weakness, or joint deformity).
3. OA is primarily a disease of cartilage that reflects a failure of the chondrocyte to maintain proper balance between cartilage formation and destruction. This leads to loss of cartilage in the joint, local inflammation, pathologic changes in underlying bone, and further damage to cartilage triggered by the affected bone.
4. The most common symptom associated with OA is pain, which leads to decreased function and range of motion. Pain relief is the primary objective of medication therapy.
5. Manifestations of OA are local, affecting one or a few joints, usually the knees, hips, and hands. Osteophytes (bony proliferation of affected joints) are often found, in contrast to the soft-tissue swelling of rheumatoid arthritis.
6. Nonpharmacologic therapy is the foundation of the pharmaceutical care plan and should be initiated before or concurrently with pharmacologic therapy.
7. Based upon efficacy, safety, and cost considerations, scheduled acetaminophen, up to 4 g/day, should be tried initially for pain relief in OA. If this fails, a nonsteroidal antiinflammatory drug (NSAID) may be tried, if there are no contraindications.
8. NSAIDs are associated with gastrointestinal (GI), renal, cardiovascular, liver, and central nervous system toxicity. Monitoring with complete blood count, serum creatinine, hepatic transaminase levels, and blood pressure readings can be valuable in detecting potential toxicity.
9. Strategies to reduce NSAID-induced GI toxicity include the use of nonacetylated salicylates, cyclooxygenase-2 (COX-2])–selective inhibitors, or the addition of misoprostol or a proton pump inhibitor. COX-2–selective inhibitors vary in their ability to prevent GI toxicity, and concomitant use of aspirin largely negates the gastroprotective effect of COX-2–selective inhibitors.
10. COX-2–selective inhibitors can increase the risk of cardiovascular events. This may be a class effect, but the extent of this risk varies among COX-2–selective inhibitors, and traditional NSAIDs may also pose risks. This hazard, in addition to the GI toxicity possible with all NSAIDs, underscores the importance of using NSAIDs only as needed and after assessing the individual patient's risk. New guidelines to reduce GI and cardiovascular risk for those who require treatment with NSAIDs have been developed.
11. Other agents useful in treating OA include topical NSAIDs or capsaicin, glucosamine and chondroitin in combination, and intraarticular injections of corticosteroids or hyaluronic acid.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

Osteoarthritis (OA) is the most common joint disease and is one of the 10 most disabling conditions in the United States and other developed nations.[1,2] Approximately 15% of the population is affected by OA, including 50% of those over 65 and 85% of those aged at least 75. The progressive destruction of articular cartilage has long been appreciated in OA, but OA involves the entire diarthrodial joint, including articular cartilage, synovium, capsule, and subchondral bone, with surrounding ligaments and muscles also playing important roles. Changes in structure and function of these tissues produce clinical OA, characterized by joint pain and tenderness, with decreased range of motion, weakness, joint instability, and disability. Knee OA alone is as important a contributor to disability as cardiovascular disease and more important than other comorbidities in this respect.

This chapter will review the epidemiology, etiology, pathogenesis, and diagnosis of OA. It then will focus on pharmacologic and nonpharmacologic treatments currently in use for OA, as well as investigational agents. Because millions of persons take medications for OA, the overall risks posed by these medications require serious consideration, particularly by clinicians who treat or advise patients on drug therapy for OA. This chapter examines the risks and benefits of OA treatments, with emphasis on those individuals who have the highest risk for adverse events, to help clinicians maximize benefit and reduce risks to their patients with OA.

EPIDEMIOLOGY

OA is the leading cause of disability in the United States.[1,3] The prevalence of arthritis-related disability is expected to increase to 11.6 million in the United States by 2020. The annual cost attributed to OA (medical care and lost wages) is estimated at $65 million in the United States.[4]

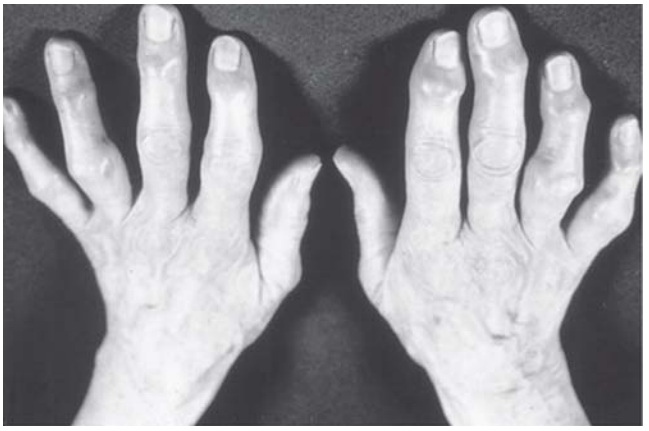

FIGURE 101-1. Heberden nodes (distal interphalangeal joint) noted on all fingers and Bouchard nodes (proximal interphalangeal joint) noted on most fingers. *(From Johnson BE. Arthritis: Osteoarthritis, Gout and Rheumatoid Arthritis. In: South-Paul JE, Matheny SC, Lewis EL, eds. Current Diagnosis and Treatment in Family Medicine. New York: McGraw-Hill; 2004:266, 267.)*

PREVALENCE BY AGE, SEX, AND RACE

1 Prevalence estimates for OA vary with age, gender, genetics, ethnic group, the specific joint involved, and methods used for diagnosis or ascertainment. Prevalence of OA increases with age. In the United States, for persons age 25 to 74, prevalence is estimated at 12%, with 60% to 70% of those over age 70 affected.[1,5] Prevalence for symptomatic knee OA is 5% for all persons over age 25, but 12% for those over 55. [1] Prevalence of symptomatic hip OA is 4%, leading to about 200,000 total hip replacements per year in the United States. Radiologically confirmed hip OA shows clear trends through all age groups, affecting 1.6% of those between ages 30 to 39, up to a prevalence of 14% in those over 85 years of age.[6] Hand OA is found in 5% of those age 40, but in 65% of those over 80 years of age.[7]

Prevalence of hip OA is 9% in white populations, but is only 4% for Asian, black, and Indian populations. Before age 50, men are more likely to have OA than women, attributed to higher rates of sports and other injuries.[4] Women exhibit a higher prevalence of hip and knee OA than men, and are at especially greater risk of hand OA, with 26% of women and 13% of men over age 70 affected.[7] Women are also more likely to have inflammatory OA of the proximal and distal interphalangeal joints of the hands, giving rise to the formation of Bouchard and Heberden nodes, respectively (Fig. 101–1).

INCIDENCE

Using a population database of approximately 4 million persons, a recent Canadian study estimated the annual incidence rate of physician-diagnosed OA in men to be 11.6 per 1000 in the period 2003 to 2004, similar to the rate of 11.3 per 1000 estimated for 1996 to 1997.[8] For women, the incidence rate significantly increased from 14.7 to 16.7 per 1000 from the period 1996 to 1997 to the period 2003 to 2004. Some of the increase observed for women could have resulted from the aging of the population and with women's longer life expectancy.

ETIOLOGY

2 The etiology of OA is multifactorial. Many patients have more than one risk factor for the development of OA. The most common risk factors for the development of OA include obesity, occupation, participation in certain sports, history of joint trauma, and a genetic predisposition. Patients with osteoporosis are also less likely to have OA, possibly due to the opposite influences of body weight on bone strength and OA risk.

OBESITY

The most important preventable risk factor for OA of the knee, hip, and hand is obesity, a particularly concerning fact given the increasing prevalence of obesity in the United States and many other countries.[1] Obesity often precedes OA and contributes to its development, rather than occurring as a result of inactivity from joint pain. In a three-decade Framingham Study, the highest quintile of body mass was associated with a higher relative risk of knee OA (relative risk of 1.5 to 1.9 for men and 2.1 to 3.2 for women).[9] Another study of 1,108 men in their twenties showed that a high body mass index was associated with later development of knee OA.[10] The risk of developing OA increases by approximately 10% with each additional kilogram of weight, and in obese persons without OA, weight loss of even 5 kg (11 lbs) decreases the risk of future knee OA by half.[9] In addition to being a risk factor for OA, obesity is also a predictor for eventual prosthetic joint replacement.

OCCUPATION, SPORTS, AND TRAUMA

OA risk is increased for those in occupations requiring prolonged standing, kneeling, squatting, lifting or moving of heavy objects, such as shipbuilding, mining, some types of factory work, carpentry, and farming.[3] Repetitive motion also contributes to hand OA, with the dominant hand usually affected.[7] Risk for OA depends on the type and intensity of physical activity. OA is associated with participation in activities such as wrestling, boxing, baseball pitching, cycling, and football, although recreational participants may not have the increased risk seen in the professional athlete. Recreational exercise (walking, jogging) by middle-aged persons did not increase or decrease risk of knee OA over 9 years of follow-up.[11]

Sports or traumatic injury to articular cartilage greatly increases OA risk.[12] Meniscal damage also increases the risk of knee OA because of the loss of proper load bearing and shock absorption, increased focal load on cartilage and on subchondral bone. Quadriceps muscle weakness also increases the risk for knee OA, as these muscles are important in maintaining joint stability.[1,4] Knee malalignment does appear to increases OA risk, but this is still under debate.[4,13,14] Knee malalignment does increase risk for faster progression of OA.[13]

Age at injury does matter, because older individuals who damage ligaments tend to develop OA more rapidly than young people with a similar injury. However, trauma that occurs early in life is significant: The incidence of knee OA by age 65 years was more than doubled for men who sustained a knee injury in adolescence compared with those who had not.[15]

GENETIC FACTORS

OA is a disease in which many genes play a role. Genetic links have been shown with OA of the first metatarsophalangeal joint and with generalized OA. Heberden nodes are 10 times more prevalent in women than in men, for example, with a twofold higher risk if the woman's mother had them. Twin studies indicate that OA can be attributed substantially to genetic factors (39% to 65%, 60%, and 70% for hand, hip, and spine OA, respectively).[16]

Genome-wide linkage studies (GWAS) (associating OA with a specific region out of the total human genome) have been used to search for the genetic basis for OA.[17] Studies based on hundreds of pedigrees from numerous countries have uncovered dozens of loci that include OA-related genes. Several other approaches are being use to link genetic influences to development or progression of OA.

Twin studies as noted above have provided clues. In other twin studies of OA progression, radiographic measurements over 2 years showed that the increased risk for a sibling having radiographic progression if the proband had progression was threefold for joint space narrowing and 1.5-fold for osteophyte progression.[18]

Using linkage analysis and other methods, genetic associations to OA include genes related to inflammation (e.g. IL1, IL-10), Wnt signaling (FRZB, LRP5), bone morphogenetic proteins (*BMP2*, *BMP5*, and *GDF5*), and proteases or their inhibitors (*ADAM12*, *TNA*, *AACT*).[17] At present, for most genes that have been identified by any method as being linked to OA, the associations have been weak or modest, even if replicable. However, recent work has shown that the risk of developing OA may be substantially determined by a combination of modest genetic differences.[19] There are now large cohorts of people with OA of the hip, knee, or multiple joints whose participation can identify specific genes important in influencing progression of OA or which identify persons at high risk for developing OA. Prospective studies are investigating factors affecting incidence and progression of knee OA including the Osteoarthritis Initiative, a multicenter, 4-year observational study of men and women, funded by the U.S. National Institutes of Health.

In addition to the importance of chromosomal DNA in OA, recent work has shown that mitochondrial DNA (inherited through the maternal route) may be important.[20] Of specific human mitochondrial DNA haplogroups, the J haplogroup was associated with a 54% reduced risk of developing OA and a 65% reduced risk of severe progression of OA, whereas haplogroup U had an 80% higher risk for severe OA progression. Given that mitochondrial DNA is important in oxidative respiration and that defects in mitochondrial respiration have been seen in OA chondrocytes, it may be that not only chromosomal DNA is important in OA, but mitochondrial DNA is as well.

PATHOPHYSIOLOGY

OA falls into two major etiologic classes. *Primary* (*idiopathic*) *OA*, the most common type, has no identifiable cause. Subclasses of primary OA are *localized OA*, involving one or two sites, and *generalized OA*, affecting three or more sites. *Erosive OA* is used to describe the presence of erosion and marked proliferation in the proximal and distal interphalangeal joints of the hands. *Secondary OA* is that associated with a known cause such as rheumatoid or another inflammatory arthritis, trauma, metabolic or endocrine disorders, and congenital factors.[3,4]

Although OA was previously considered a wear-and-tear disease, increased knowledge of articular cartilage has led to a more dynamic understanding of OA. Some changes in the OA joint may reflect compensatory processes to maintain function in the face of ongoing joint destruction. Not only biomechanical forces but also inflammatory, biochemical, and immunologic factors are involved. Understanding the biology and function of normal cartilage aids in understanding OA and is summarized below.

NORMAL CARTILAGE

Function, Structure, and Composition of Cartilage

Articular cartilage possesses viscoelastic properties that provide lubrication with motion, shock absorbency during rapid movements, and load support. In synovial joints, articular cartilage is found between the synovial cavity on one side and a narrow layer of calcified tissue overlying subchondral bone on the other side (Fig. 101–2).[21] The layer of cartilage is narrow with human medial femoral articular cartilage being approximately 2 to 3 mm thick. Despite this, healthy articular cartilage in weight-bearing joints withstands millions of cycles of loading and unloading each year. Cartilage is easily compressed, losing up to 40% of its original height when a load is applied. Compression increases the area of contact and disperses force more evenly to underlying bone, tendons, ligaments, and muscles. In addition, cartilage is almost frictionless, and together with its compressibility, this enables smooth movement in the joint, distributes load across joint tissues to prevent damage, and stabilizes the joint.

Strength, a low coefficient of friction, and compressibility of cartilage derive from its unique structure. Cartilage is composed of a complex, hydrophilic, extracellular matrix (ECM). It is approximately 75% to 85% water and 2% to 5% chondrocytes (the only cells in cartilage), and it contains collagen proteins, smaller amounts of several other proteins, proteoglycans, and long hyaluronic acid molecules.[21] The two major structural components in articular cartilage are type II collagen and aggrecans.[22] Type II collagen has a tightly woven triple helical structure, which provides the tensile strength of cartilage. Aggrecan is a proteoglycan linked with hyaluronic acid, providing the long aggrecan molecules a high negative charge. These are squeezed together by surrounding fibrils of type II collagen. The strong electrostatic repulsion of proteoglycans held in close proximity gives cartilage the ability to withstand further compression. Within the cartilage ECM are the chondrocytes, responsible for laying down all the components of cartilage.

Normal cartilage turnover helps repair and restore cartilage and thus respond to the usual demands put on cartilage by loading and physical activity. In healthy adult cartilage, chondrocyte metabolism is slow, with a dynamic balance between anabolic processes. This metabolism is promoted by growth factors, including bone morphogenetic protein 2, insulin-like growth factor-1, transforming growth factor, by catabolism and proteolysis stimulated by matrix metalloproteinases (MMPs), tumor necrosis factor-α (TNF-α, interleukin-1, and other cytokines. Tissue inhibitors

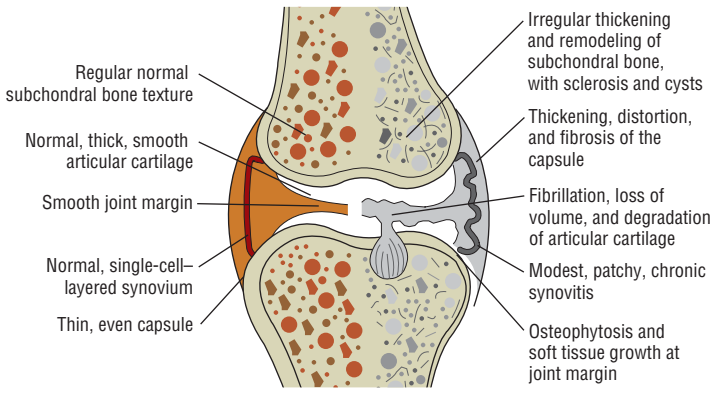

FIGURE 101-2. Characteristics of osteoarthritis in the diarthrodial joint. *(Courtesy of Dr. D. Gotlieb.)*

of metalloproteinase (TIMP) also contribute to the balance by restraining the catabolic actions of MMPs. If cartilage is injured, chondrocytes react by removing the damaged areas and increasing synthesis of matrix constituents to repair and restore cartilage.

Another component supporting healthy joints are the joint protective mechanisms, such as muscles bridging the joint, sensory receptors in feedback loops to regulate muscle and tendon function, supporting ligaments, and subchondral bone that has shock-absorbent properties.

Finally, it is important to note that adult articular cartilage is avascular, with chondrocytes nourished by synovial fluid. With movement and cyclic loading and unloading of joints, nutrients flow into the cartilage, whereas immobilization reduces nutrient supply. This is one of the reasons that normal physical activity is beneficial for joint health.

OSTEOARTHRITIC CARTILAGE

3 Important contributors to the development of OA are local mechanical influences, genetic factors, inflammation, and aberrant chondrocyte function leading to loss of articular cartilage. At a molecular level, OA pathophysiology involves the interplay of dozens, if not hundreds, of extracellular and intracellular molecules with roles including chondrocyte regulation, phenotypic changes, proteolytic degradation of cartilage components, and interactions between articular cartilage, underlying subchondral bone, and the joint synovium.

OA most commonly begins with damage to articular cartilage, through trauma or other injury, excess joint loading from obesity or other reasons, or instability or injury of the joint that causes abnormal loading. In response to cartilage damage, chondrocyte activity increases in an attempt to remove and repair the damage. Depending on the degree of damage, the balance between breakdown and resynthesis of cartilage can be lost, and a vicious cycle of increasing breakdown can lead to further cartilage loss.[1,12,22,23] Destruction of aggrecans by the proteolytic enzyme (ADAMTS-5) is considered to play a key role. Recent work suggests the involvement of a collagen receptor, named *DDR-2*, located on the chondrocyte cell surface.[24] In healthy cartilage, DDR-2 is inactive, masked from contact with collagen by aggrecans. Damage to cartilage triggers aggrecans destruction, thus exposing DDR-2 to collagen. The active DDR-2 then increases activity of MMP-13, which destroys collagen. Collagen breakdown products then further stimulate DDR-2, with a vicious circle in which more collagen is destroyed and cartilage.

Other mechanisms contribute to the initiation and perpetuation of cartilage loss. Further insights into the complex process have been gained by research showing the following:

1. Expression of hundreds of specific genes are affected by acute experimental injury of human cartilage tissue, that is, injury alters the chondrocyte phenotype.[25]
2. Within different regions of human OA cartilage obtained at surgery, chondrocyte gene expression from the most damaged areas of cartilage is different from that from less damaged or normal areas.[26]
3. Comparative proteomics of articular cartilage from normal persons compared with those with OA showed different expression.[27]

Finally, some of the changes seen soon after acute cartilage damage are the same changes that have been seen in OA as compared with normal cartilage. Such studies should provide valuable clues to explain the mechanism of cartilage loss and potentially identify targets for drug development.

In addition to changes taking place in OA cartilage, there is also a role in OA for the subchondral bone adjacent to articular cartilage.

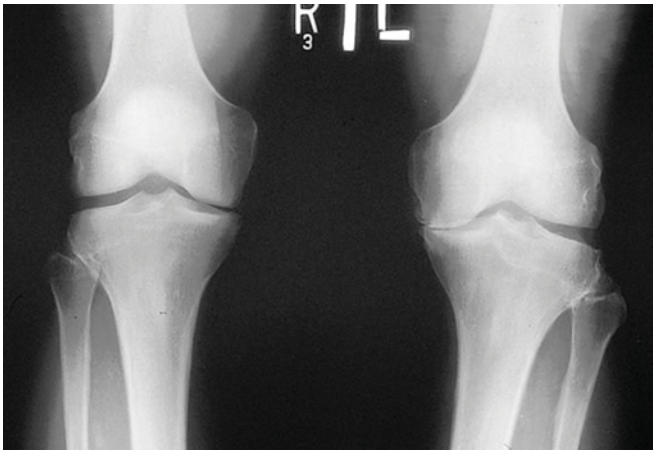

FIGURE 101-3. Plain x-ray films of the knee demonstrating joint space narrowing. *(From Johnson BE. Arthritis: Osteoarthritis, Gout and Rheumatoid Arthritis. In: South-Paul JE, Matheny SC, Lewis EL, eds. Current Diagnosis and Treatment in Family Medicine. New York: McGraw-Hill; 2004:267.)*

Subchondral bone undergoes pathologic changes that may precede, coincide with, or follow damage to the articular cartilage. This damage to subchondral bone may play an essential role in allowing damage to articular cartilage to progress.[28] In OA, subchondral bone releases vasoactive peptides and MMPs. Neovascularization and subsequent increased permeability of the adjacent cartilage occur and contributes further to cartilage loss.

Substantial loss of cartilage causes joint space narrowing and leads to a painful, deformed joint (Fig. 101–3). Furthermore, the remaining cartilage softens and develops fibrillations (vertical clefts into the cartilage), and there is splitting, further loss of cartilage, and exposure of underlying bone.[2] As cartilage is destroyed and the adjacent subchondral bone undergoes pathologic changes, cartilage is eroded completely, leaving denuded subchondral bone, which becomes dense, smooth, and glistening (eburnation). A more brittle, stiffer bone results, with decreased weight-bearing ability and development of sclerosis and microfractures. New bone formations, or osteophytes, also appear at joint margins distant from cartilage destruction and are thought to arise from local and humoral factors. There is direct evidence that osteophytes can help stabilize osteoarthritic joints.[29]

Accompanying the changes in cartilage and subchondral bone, local inflammatory changes and pathologic changes can occur in the joint capsule and synovium. Infiltration of the synovium with T cells with T-helper type 1 phenotype occurs, as well as the appearance of immune complexes.[16] Contributors to this inflammation may include crystals or cartilage shards in synovial fluid. With increased levels of interleukin-1, prostaglandin E_2, TNF-α, and nitric oxide observed in synovial fluid, these agents could also play a role.[29,30] With inflammatory changes in the synovium, effusions and synovial thickening occur.

4 The pain of OA is not related to the destruction of cartilage but arises from the activation of nociceptive nerve endings within the joint by mechanical and chemical irritants.[1] OA pain may result from distension of the synovial capsule by increased joint fluid, microfracture, periosteal irritation, or damage to ligaments, synovium, or the meniscus.

CLINICAL PRESENTATION

DIAGNOSIS

5 The diagnosis of OA is made through history, physical examination, characteristic radiographic findings, and laboratory testing.[3,4] The major diagnostic goals are (1) to discriminate between primary

and secondary OA and (2) to clarify the joints involved, severity of joint involvement, and response to prior therapies, providing a basis for a treatment plan. The American College of Rheumatology has published traditional diagnostic criteria and "decision trees" for OA diagnosis.[31] As for all guidelines, the authors stress these are for assisting the clinician rather than replacing clinical judgment. For example, traditional criteria are as follows: (1) For hip OA, a patient must have pain in the hip and at least two of the following three: an erythrocyte sedimentation rate <20 mm/h (<5.6 μm/s), femoral or acetabular osteophytes on radiography, or joint space narrowing on radiography. This provides a sensitivity of 89% and a specificity of 91%. (2) For knee OA, a patient must have pain at the knee and osteophytes on radiography plus one of the following: age older than 50 years, morning stiffness no more than 30 minutes, crepitus on motion, bony enlargement, bony tenderness, or palpable warmth. This provides a sensitivity of 95% and a specificity of 69%. The addition of laboratory or radiographic data further improves accuracy of diagnosis. Criteria for hand OA have also been published.[32]

CLINICAL PRESENTATION OF OSTEOARTHRITIS

Age

- Usually elderly

Gender

- Age <45 more common in men
- Age >45 more common in women

Symptoms

- Pain
- Deep, aching character
- Pain on motion
- Pain with motion early in disease
- Pain with rest late in disease
- Stiffness in affected joints
- Resolves with motion, recurs with rest ("gelling" phenomenon)
- Usually duration <30 minutes
- Often related to weather
- Limited joint motion
- May result in limitations activities of daily living
- Instability of weight-bearing joints

Signs, history, and physical examination

- Monarticular or oligoarticular; asymmetrical involvement
- Hands
- Distal interphalangeal joints
- Heberden nodes (osteophytes or bony enlargements) (Fig. 101–1)
- Proximal interphalangeal joints
- Bouchard's nodes (osteophytes)
- First carpometacarpal joint
- Osteophytes give characteristic square appearance of the hand (shelf sign)
- Knees
- Patellofemoral compartment involvement
- Pain related to climbing stairs
- Medial compartment involvement
- Genu varum (bowlegged deformity)
- Lateral compartment involvement
- Genu valgum (knock-kneed deformity)
- Transient joint effusions
- Typically noninflammatory synovial fluid (WBC <2000/mm^3 [<2 × 10^9/L])
- Hips
- Groin pain during weight-bearing activities
- Stiffness, especially after inactivity
- Limited joint motion
- Spine
- L3 and L4 involvement is most common in the lumbar spine
- Signs and symptoms of nerve root compression
- Radicular pain
- Paresthesias
- Loss of reflexes
- Muscle weakness associated with the affected nerve root
- Feet
- Typically involves the first metatarsophalangeal joint
- Other sites, less commonly involved
- Shoulder, elbow, acromioclavicular, sternoclavicular, and temporomandibular joints

Observation on joint examination

- Bony proliferation or occasional synovitis
- Local tenderness
- Crepitus
- Muscle atrophy
- Limited motion with passive/active movement
- Deformity

Radiologic evaluation

- Early mild OA
- Radiographic changes often absent
- Progression of OA
- Joint space narrowing
- Subchondral bone sclerosis
- Marginal osteophytes
- Late OA
- Abnormal alignment of joints
- Effusions

Characteristics of synovial fluid

- High viscosity
- Mild leukocytosis (<2000 WBC/mm^3 [<2 × 10^9/L])

Laboratory values

- No specific test
- Erythrocyte sedimentation rate and hematologic and chemistry survey are normal

PROGNOSIS

The prognosis for patients with primary OA is variable and depends on the joint involved. If a weight-bearing joint or the spine is involved, considerable morbidity and disability are possible. In the case of secondary OA, the prognosis depends on the underlying cause. Treatment of OA may relieve pain or improve function but does not reverse preexisting damage to the articular cartilage.

TREATMENT

Osteoarthritis

DESIRED OUTCOME

Management of the patient with OA begins with a diagnosis based on a careful history, physical examination, radiographic findings, and an assessment of the extent of joint involvement. Treatment should be tailored to each individual. Goals are (1) to educate the patient, family members, and caregivers; (2) to relieve pain and stiffness; (3) to maintain or improve joint mobility; (4) to limit functional impairment; and (5) to maintain or improve quality of life.[3,33–36]

General Approach to Treatment

Treatment for each OA patient depends on the distribution and severity of joint involvement, comorbid disease states, concomitant medications, and allergies (Fig. 101–4). Management for all individuals with OA should begin with patient education, physical and/or occupational therapy, and weight loss or assistive devices if appropriate.[3,34–36]

The primary objective of medication is to alleviate pain.[3,34–37] Scheduled acetaminophen, up to 4 g/day, should be tried initially. If this is ineffective, nonsteroidal antiinflammatory drugs (NSAIDs) are prescribed, or possibly a cyclooxygenase-2 (COX-2)–selective inhibitor (celecoxib) if warranted. Application of capsaicin or topical NSAID creams over specific joints can be helpful adjuncts for pain control. Joint aspiration followed by glucocorticoid can relieve pain and is offered concomitantly with oral analgesics or after their lack of efficacy, depending on the practitioner's preference. Opioid analgesics are a final medication to prescribe if other therapies are unsuccessful. When symptoms are intractable or there is significant loss of function, joint replacement may be appropriate if the patient is a surgical candidate.

Finally, for patients interested in clinical trials, investigational strategies with oral doxycycline, MMP inhibitors, disease-modifying *OA* drugs, or cartilage transplantations may be considered.

For management of patients with OA, the Third Canadian Consensus Conference Group recently summarized evidence-based recommendations (Table 101–1).[38] As with all guidelines, these are for assisting the clinician rather than replacing the clinician's judgment based on the patient's characteristics. The American College of Rheumatology, as well as others, recommends acetaminophen as the drug of first choice.[36,39,40] For patients with risk factors for GI complications, selection of a nonselective NSAID plus a proton pump inhibitor (PPI) or a COX-2–selective inhibitor plus a PPI is supported by much recent evidence, as described in this chapter.

NONPHARMACOLOGIC THERAPY

6 The first step in OA treatment is patient education about the disease process, the extent of OA, the prognosis, and treatment options. Education is paramount in that OA is often seen as a wear-and-tear disease, an inevitable consequence of aging for which nothing helps. Even worse, patients may resort to the use of alternative but unproven medications or quackery. Patients should be warned about these and encouraged to access information from local or national units of the Arthritis Foundation.[41] The Arthritis Foundation provides literature about OA and OA medications and information about local clinics and agencies offering physical and economic assistance. The Arthritis Foundation also sponsors support groups and public education programs.

The benefits of patient education have been documented in a variety of programs. These programs are provided across a wide spectrum of delivery methods: from trained volunteers using telephone calls to group sessions for patient support to one-on-one educational sessions with physical therapists or nurse educators. While nearly all of these delivery methods are effective, cost of delivery is highly variable. Long-term cost-effectiveness is very important for sustainability of these patient education programs.

Diet

Excess weight increases the biomechanical load on weight-bearing joints and is the single best predictor of need for eventual joint replacement.[10,42–44] Even a 5 kg (11 lb) weight loss can decrease the load on a weight-bearing joint. Weight loss is associated with decreased symptoms and disability, although results are variable.[42,44,45] At least one randomized, controlled trial has demonstrated improvement in pain and self-reported physical function using a combination of modest weight loss (5%) and exercise.[46] There is a large weight-loss trial under way, The Intensive Diet and Exercise for Arthritis trial (IDEA), that will address weight-related joint loading and inflammatory biomarkers.[47] Although weight loss requires a motivated patient, it should be encouraged and supported for all overweight patients with OA.

Physical and Occupational Therapy

Physical therapy—with heat or cold treatments and an exercise program—helps to maintain and restore joint range of motion and to reduce pain and muscle spasms. Warm baths or warm water soaks may decrease pain and stiffness. Heating pads should be used with caution, especially in the elderly. Patients should be warned not to fall asleep on the heat source or to lie on it for more than brief periods to avoid burns.

Exercise programs and quadriceps strengthening can improve physical functioning and can decrease disability, pain, and analgesic use by OA patients.[46,48] Isometric exercise is preferred over isotonic exercise because the latter can aggravate affected joints. Exercises should be taught and then observed before the patient exercises at home, ideally three to four times daily. The patient should be instructed to decrease the number of repetitions if severe pain develops with exercise.

The decision about whether to encourage walking should be made on an individual basis. With weak or deconditioned muscles, the load is transmitted excessively to the joints; so weight-bearing activities can exacerbate symptoms. However, avoidance of activity by those with hip or knee OA leads to further deconditioning or weight gain. A program of patient education, muscle stretching and strengthening, and supervised walking can improve physical function and decrease pain for patients with knee OA.[48] Referral to the physical and/or occupational therapist is especially helpful for patients with functional disabilities. The therapist can assess muscle strength and joint stability and recommend exercises and methods of protecting the affected joint from excessive forces. The therapist can also provide assistive and orthotic devices, such as canes, walkers, braces, heel cups, splints, or insoles for use during exercise or daily activities.

Surgery

Surgery can be recommended for OA patients with functional disability and/or severe pain unresponsive to conservative therapy. Criteria for total joint replacement (arthroplasty) of the knee were developed at an National Institutes of Health consensus conference.[49] Likewise, criteria for total hip replacement, as well as a summary of clinical outcomes resulting from this procedure have

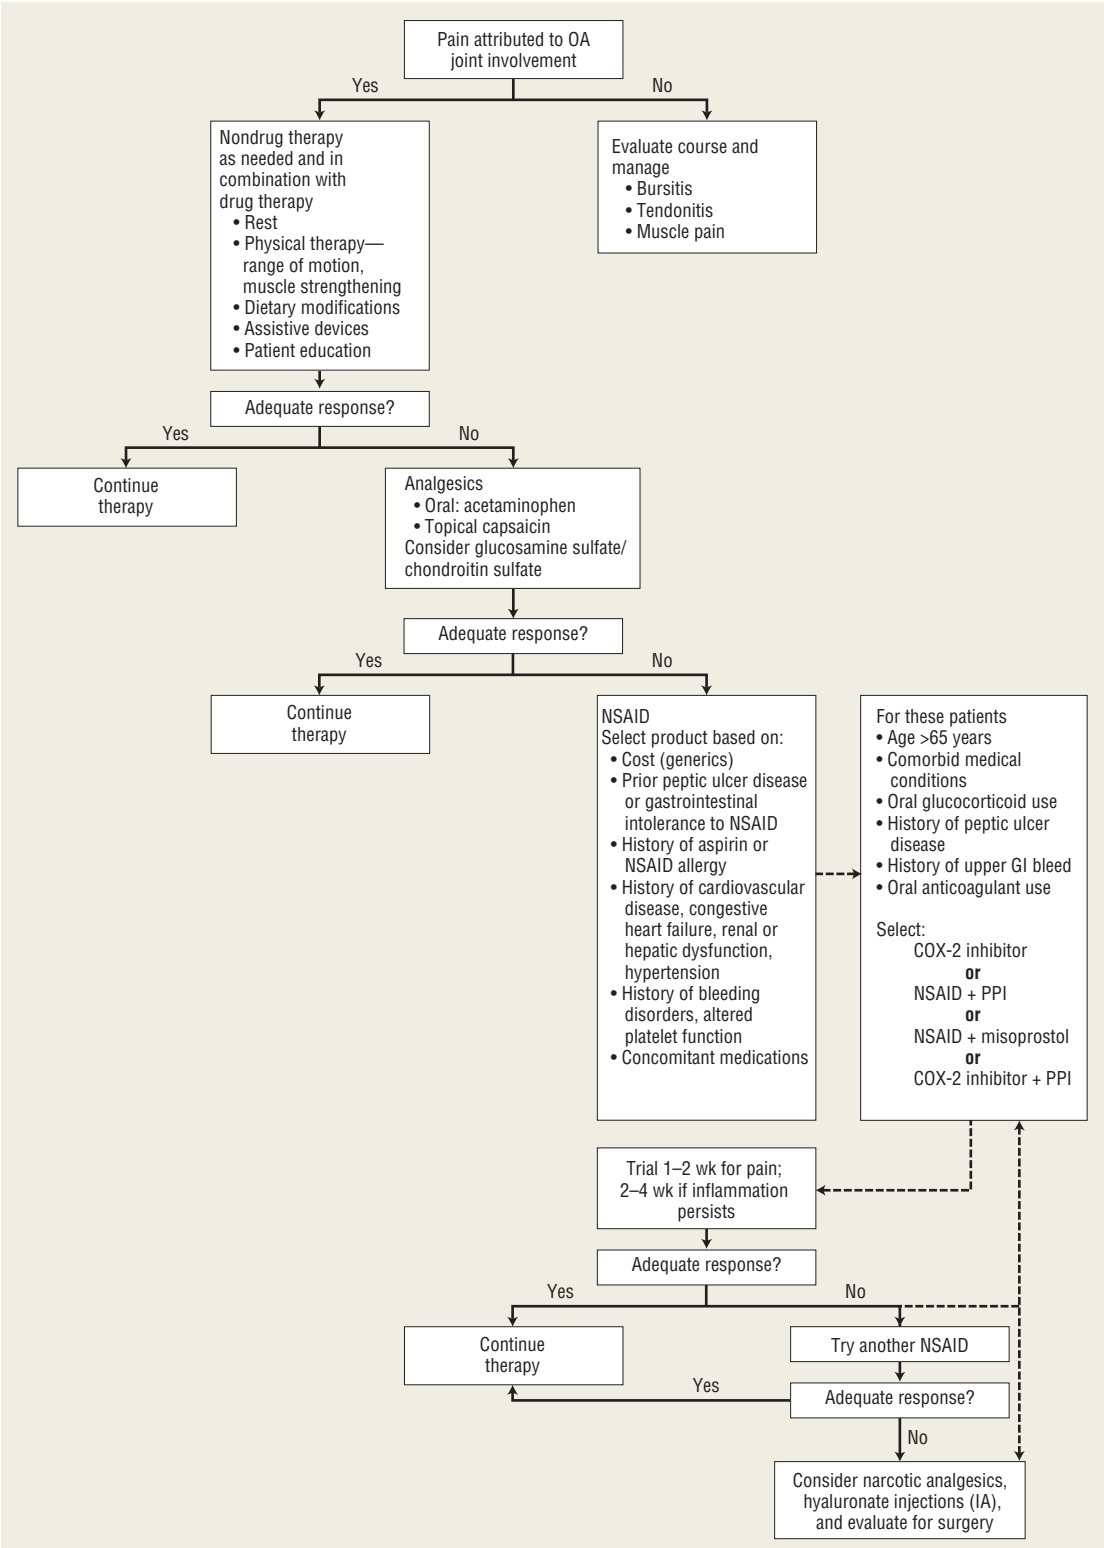

FIGURE 101-4. Treatment algorithm for osteoarthritis. (COX, cyclooxygenase; GI, gastrointestinal; IA, intraarticular; NSAID, nonsteroidal antiinflammatory drug; OA, osteoarthritis; PPI, proton pump inhibitor.)

been published.[50] These hip and knee replacement recommendations have been based on critical review of the literature as well as on expert opinion. For patients with advanced disease, a partial or total arthroplasty can relieve pain and improve motion, with the best outcomes after total hip or knee arthroplasty. Total joint arthroplasty is responsible for a large portion of the direct medical costs associated with OA in the United States.

Recently, the cost-effectiveness of total knee arthroplasty has been evaluated for a Medicare-age population.[51] Calculations were based on Medicare claims data and costs and outcomes data. Cost projections were calculated for lifetime costs as well as quality-adjusted life expectancy (QALE) for different risk populations and across low-volume to high-volume hospitals. Although total knee arthroplasty was found to be cost-effective across hospital settings

TABLE 101-1 Recommendations for Osteoarthritis[a]

Recommendation		Level of Evidence	Grade of Recommendation
1. Patient-physician communication	Patients should be fully informed about evolving information regarding the benefits and risks of their treatment options.	3	C
2. Indications	NSAIDs and coxibs are generally more effective and preferred by patients over acetaminophen, although a trial of the latter is warranted for some patients. Topical NSAID formulations may confer benefit in knee OA	1	A
3. GI toxicity	For patients with risk factors for PUB, a coxib is still the antiinflammatory drug of choice, depending on the patient's cardiovascular risks. High-risk patients who must use nonselective NSAIDs should have a PPI.	1	A
4. Renal	Before starting an NSAID or coxib, determine renal status and creatinine clearance for patients over age 65 years or for those with comorbid conditions that may affect renal function. Advise patients that if they can not eat or drink that day, they should withhold that day's dose of NSAID/coxib.	3 4	C D
5. Hypertension	For patients receiving antihypertensive drugs, measure blood pressure within a few weeks after initiating NSAID/coxib therapy and monitor appropriately; drug doses may need adjustment.	1	A
6. Cardiovascular	Patients taking rofecoxib have been shown to have an increased risk of CV events. Current data suggest that this increased CV risk may be an effect of the NSAID/coxib class. Physicians and patients should weigh the benefits and risks of NSAID/coxib therapy.	1	A
7. Geriatric consideration	NSAIDs/coxibs should be used with caution in elderly patients, who are at the greatest risk for serious GI, renal, and CV side effects.	3	C
8. Pharmacoeconomics	Although the data are ambiguous, coxibs may be more cost-effective than traditional NSAID + proprietary PPI among high-risk patients.	3	C

NSAID, nonsteroidal antiinflammatory drug; GI, gastrointestinal; CV, cardiovascular; PUB, perforations, ulcers, and bleeds; PPI, proton pump inhibitor.

Categories of evidence: 1A, metaanalysis of RCT; 1B, at least one RCT; 2A, at least one controlled study without randomization; 3, descriptive studies, such as comparative, correlation, or case-control studies; 4, expert committee reports or opinions and/or clinical experience of respected authorities.

Grades of recommendations: A, category 1 evidence; B, category 2 evidence or extrapolated recommendation from category 1 evidence; C, category 3 evidence or extrapolated recommendation from category 1 or 2 evidence; D, Category 4 evidence or extrapolated recommendation from category 2 or 3 evidence.

From Table 4, p. 153, of reference 38. Reprinted with permission from the Journal of Rheumatology and the author.

and patient risk category, the procedure was found to be most cost-effective when performed in high-volume centers.

Other surgical options are also available. Arthrodesis (joint fusion) can reduce pain but will restrict motion and may be appropriate for smaller joints that are causing intractable pain. For patients with mild knee OA, an osteotomy (removal of bony tissue) may correct the misalignment of genu varum ("bowlegged" knees) or genu valgum ("knock-knees"). In addition, osteotomies of the pelvis or femur can ameliorate joint misalignment in hip OA, subsequently slowing progression of disease. Knee arthroscopy or lavage appear to be equivalent to sham surgery and are not recommended.[39] Experimental but potentially restorative approaches involve soft-tissue grafts, chondrocyte transplantation, gene therapy, and use of growth factors or artificial matrices.[52] Cartilage-restoration approaches are investigational, and results regarding pain control and joint function have been mixed.

PHARMACOLOGIC THERAPY

Drug therapy in OA is targeted at relief of pain. OA is commonly seen in older individuals who have other medical conditions, and OA treatment is often long term. As such, a conservative approach to drug treatment, focusing on the needs of the individual patient, is warranted (see Fig. 101–3). For mild or moderate pain, topical analgesics or acetaminophen can be used. If these measures fail, or if there is inflammation, NSAIDs may be useful. Even when drug therapy is initiated, appropriate nondrug therapies should be continued and reinforced. Nondrug modalities are the cornerstone of OA management and may provide as much relief as drug therapy.

Acetaminophen

Place in Therapy 7 The American College of Rheumatology as well others recommend acetaminophen as first-line drug therapy for pain management in OA because of its relative safety, efficacy, and lower cost compared with NSAIDs.[36,39,40] Pain relief with acetaminophen has been reported as similar to that obtained with aspirin, naproxen, ibuprofen, and other NSAIDs, although many patients respond better to NSAIDs.[36,39,40] In addition to guidelines from the American College of Rheumatology, recommendations for OA management have been published by The European League Against Rheumatism, the Osteoarthritis Research International (OARSI), and the American Academy of Orthopedic Surgeons.[36,39,40] All of these guidelines stress the importance of acetaminophen as first-line drug therapy for OA.

Pharmacology and Mechanism of Action Acetaminophen is understood to act within the central nervous system (CNS) by inhibiting synthesis of prostaglandins, agents that enhance pain sensations. Acetaminophen prevents prostaglandin synthesis by blocking the action of central cyclooxygenase (COX). Acetaminophen is well absorbed after oral administration, with a bioavailability of 60% to 98%. It achieves peak concentrations within 1 to 2 hours, it is inactivated in the liver by conjugation with sulfate or glucuronide, and its metabolites are renally excreted.

Efficacy Comparable relief of mild to moderate OA pain has been demonstrated for acetaminophen at 2.6 to 4 g/day, aspirin 650 mg four times daily, and NSAIDs, including ibuprofen at 1,200 or 2,400 mg daily, and naproxen 750 mg daily.[40,53] Although studies have shown comparable efficacy for acetaminophen and NSAIDs, several others have reported that patients experience better pain control with NSAIDs than with acetaminophen.[40,53,54] Patients with OA have been shown to prefer NSAIDs compared with acetaminophen in clinical trials, but when queried using a questionnaire that included considerations of side effects, NSAIDs were less preferred by patients.[55]

Adverse Effects Although acetaminophen is one of the safest analgesics, its use carries some risks, primarily hepatotoxicity and possibly renal toxicity with long-term use.[33,56] Serious hepatotoxicity, including fatalities, have been well documented with acetaminophen overdose (see Chap. 14 for treatment of acetaminophen overdose). Continued reports of serious hepatotoxicity, including fatalities from unintentional overdose, have led to labeling revisions of all nonprescription acetaminophen containing analgesics.[57] Unintentional overdoses of acetaminophen are due to a variety

of circumstances including narrow therapeutic window at the maximum dose (4 g/day), interpatient differences in sensitivity to liver injury from acetaminophen, a wide array of nonprescription and prescription products that contain acetaminophen, which may be hard for patients to identify on the label, and consumers' lack knowledge about the association of acetaminophen and liver injury.

CLINICAL CONTROVERSY

In June 2009, an FDA Advisory Committee recommended restrictions on acetaminophen dosing ranges and product availability and enhancements to approved drug labeling to highlight issues related to acetaminophen overdose and hepatotoxicity. The specific recommendations include decreasing the single adult dose and the maximum daily dose of nonprescription acetaminophen, allowing only one concentration of liquid acetaminophen, adding a black-box warning to the labeling, and, most controversial, eliminating prescription combination acetaminophen/opioid (e.g. Vicodin™, Percocet™) products from the market. While the FDA is not required to follow the recommendations of the Advisory Committee, it often does so. As of spring 2010, the FDA has yet to formally rule on these recommendations.

In a study of normal, healthy volunteers administered acetaminophen 4 g/day (1 g every 6 hours), alone or with concomitant opioid therapy, for 14 days, elevations of alanine aminotransferase at levels above three times the upper limits of normal were found in 31% to 44% of patients, depending on treatment group.[58] None of these participants had clinical symptoms of acute liver disease. Although the results of this study are not robust enough to alter the current standard dosing recommendations, it serves as an important reminder that the maximum dose of acetaminophen should be not be exceeded in any patient population and that chronic use of the maximum daily dose of 4 g/day can affect the liver. Acetaminophen should be used cautiously for patients with liver disease or for those who abuse alcohol. Acute liver failure has been reported for patients taking less than 4 g/daily.[59] The most common risk factor for liver failure for these patients was chronic alcohol intake. The FDA has recommended that chronic alcohol users (three or more drinks daily) should be warned regarding an increased risk of liver damage or GI bleeding with acetaminophen. Other individuals do not appear to be at increased risk of GI bleeding.

The National Kidney Foundation strongly discourages the use of nonprescription combination analgesic products (e.g., acetaminophen and NSAIDs) because this is associated with an increased prevalence of renal failure.[56]

Drug–Drug Interactions and Drug–Food Interactions Drug interactions with acetaminophen can occur; for example, isoniazid can increase the risk of hepatotoxicity. Chronic ingestion of maximal doses of acetaminophen may intensify the anticoagulant effect for patients taking warfarin; such individuals may need closer monitoring. Although food decreases the maximum serum concentration of acetaminophen by approximately half, the overall efficacy is unchanged.

Dosing and Administration When used for chronic OA, acetaminophen should be administered in a scheduled manner. It may be taken with or without food. Acetaminophen can be taken at 325 to 650 mg every 4 to 6 hours, but the total dose must not exceed 4 g daily (see Adverse Effects above). New labeling requirements will warn patients about potential toxicity if they inadvertently ingest more than the recommended dose when using multiple products containing acetaminophen. If acetaminophen is used in the setting of chronic alcohol intake or in those with underlying liver disease, the duration should be limited, and the dose should not exceed 2 g daily

Nonsteroidal Antiinflammatory Drugs

Place in Therapy The American College of Rheumatology, the Third Canadian Consensus Conference Group, the Osteoarthritis Research Society International, and other organizations recommend consideration of NSAIDs for OA patients in whom acetaminophen is ineffective. Nonselective NSAIDS and COX-2–selective NSAIDS are superior to acetaminophen for improving symptoms and functional limitations.[60] Nonselective NSAIDs and COX-2–selective NSAIDs all display comparable analgesic and antiinflammatory efficacy and are similarly beneficial in OA (Table 101–2).[60–62]

Pharmacology and Mechanism of Action Blockade of prostaglandin synthesis by inhibiting COX enzymes (COX-1 and COX-2) accounts for NSAIDs' ability to relieve pain and inflammation (Fig. 101–5).[60,63–65] Because nonspecific NSAIDs and COX-2–selective inhibitors have similar efficacy, drug selection often depends on toxicity and cost. There is increasing concern regarding safety of all nonselective and COX-2–selective NSAIDs, particularly in the GI and cardiovascular areas. The next section will review the differences between nonspecific NSAIDs and COX-2–selective inhibitors.

Nonspecific NSAIDs and COX-2–Selective Inhibitors The COX-1 enzyme participates in "housekeeping" or routine physiologic functions such as generation of gastroprotective prostaglandins to promote gastric blood flow and bicarbonate generation (see Fig. 101–5).[60,64] COX-1 is expressed constitutively not only in gastric mucosa but also in vascular endothelial cells, platelets, and renal collecting tubules so that COX-1–generated prostaglandins and thromboxane also participate in hemostasis and renal blood flow. In contrast, the COX-2 enzyme is not as widely expressed in most body tissues but is rapidly induced by inflammatory mediators, local injury, and cytokines including interleukins, interferon, and TNF. Prostaglandins made by COX-2 contribute to pain sensations in OA and other conditions. Prostaglandins made by the COX-2 enzyme, including prostacyclin (prostaglandin I_2) are also implicated in some physiologic processes, including renal function, tissue repair, reproduction, and development.

Nonspecific NSAIDs block both COX-1 and COX-2 enzymes. COX-1 blockade with nonspecific NSAIDs can lead to GI ulcers and increased bleeding risk by inhibiting platelet aggregation.[60,64,65] COX-2–selective agents ("coxibs") were developed to exploit these agents' ability to reduce prostaglandins, inflammation, and pain, without blocking effects of COX-1. These agents are efficacious in relieving OA and other pain, and some do have improved GI safety. Celecoxib was the first COX-2–selective agent marketed and has been widely used for pain relief in OA and other conditions.[60,62] Rofecoxib was withdrawn from the worldwide market over concern about increased cardiovascular risk. Valdecoxib was withdrawn due to concerns about cardiovascular safety and about serious skin reactions, including deaths. Lumiracoxib and etoricoxib are not FDA approved but are marketed in several other countries; lumiracoxib has been withdrawn from the market in the United Kingdom and Australia.

It is now appreciated that the COX-2 enzyme may play an important physiologic role in normal hemostasis. The COX-2 enzyme, found in blood vessel endothelial cells, leads to production of prostaglandin I_2 (prostacyclin), which has antithrombotic effects. The COX-1 found in platelets forms thromboxane A_2 a prothrombotic molecule. Thus, blocking COX-2 alone could upset the hemostatic

TABLE 101-2 Medications Commonly Used in the Treatment of Osteoarthritis

Medication	Dosage and Frequency	Maximum Dosage (mg/day)
Oral analgesics		
Acetaminophen	325–650 mg every 4–6 hours or 1 g 3–4 times/day	4,000
Tramadol	50–100 mg every 4–6 hours	400
Acetaminophen/codeine	300 to 1000 mg/15 to 60 mg every 4 hours as needed	4,000 mg/360mg[a]
Acetaminophen/oxycodone	325 to 650 mg/2.5 to 10 mg every 6 hours as needed	4,000 mg/40mg[a]
Topical analgesics		
Capsaicin 0.025% or 0.075%	Apply to affected joint 3–4 times per day	
Nutritional supplements		
Glucosamine HCl/chondroitin sulfate	500mg/400 mg 3 times/day	1,500/1,200
Nonsteroidal antiinflammatory drugs (NSAIDs)		
Carboxylic acids		
Acetylated salicylates		
Aspirin, plain, buffered, or enteric coated	325–650 mg every 4–6 hours for pain; antiinflammatory doses start at 3,600 mg/day in divided doses	3,600[b]
Nonacetylated salicylates		
Salsalate	500–1,000 mg 2–3 times a day	3,000[b]
Diflunisal	500–1,000 mg 2 times a day	1,500
Choline salicylate[c]	500–1,000 mg 2–3 times a day	3,000[c]
Choline magnesium salicylate	500–1,000 mg 2–3 times a day	3,000[c]
Acetic acids		
Etodolac	800–1200 mg/day in divided doses	1,200
Diclofenac	100–150 mg/day in divided doses	200
Indomethacin	25 mg 2–3 times a day; 75 mg SR once daily	200; 150
Ketorolac[d]	10 mg every 4–6 hours	40
Nabumetone[e]	500–1,000 mg 1–2 times a day	2,000
Propionic acids		
Fenoprofen	300–600 mg 3–4 times a day	3,200
Flurbiprofen	200–300 mg/day in 2–4 divided doses	300
Ibuprofen	1,200–3,200 mg/day in 3–4 divided doses	3,200
Ketoprofen	150–300 mg/day in 3–4 divided doses	300
Naproxen	250–500 mg twice a day	1,500
Naproxen sodium	275–550 mg twice a day	1,375
Oxaprozin	600–1,200 mg daily	1,800
Fenamates		
Meclofenamate	200–400 mg/day in 3–4 divided doses	400
Mefenamic acid[f]	250 mg every 6 hours	1,000
Oxicams		
Piroxicam	10–20 mg daily	20
Meloxicam	7.5 mg daily	15
Coxibs		
Celecoxib	100 mg twice daily or 200 mg daily	200 (400 for RA)

[a]Maximum dosage in combination product limited by acetaminophen maximum of 4,000 mg/d.
[b]Monitor serum salicylate levels over 3 to 3.6 g/day.
[c]Only available as a liquid; 870 mg salicylate/5 mL.
[d]Not approved for treatment of OA for more than 5 days.
[e]Nonorganic acid but metabolite is an acetic acid.
[f]Not approved for treatment of OA.
RA, rheumatoid arthritis; SR, sustained release.

balance, in favor of thromboxane A_2, with prothrombotic events possible.[64–66] Whether the "prothrombotic imbalance" explanation causes the increased cardiovascular risk seen with COX-2–selective inhibitors remains unknown.[64–66] Celecoxib carries a black-box warning for cardiovascular and GI risks, as do other NSAIDs at this time.

Pharmacokinetics

The various NSAIDs exhibit several pharmacokinetic similarities, including high oral availability, high protein binding, and absorption as active drugs (except for sulindac and nabumetone, which require hepatic conversion for activity). The most important difference in NSAIDs is a serum half-life ranging from 1 hour for tolmetin to 50 hours for piroxicam, impacting the frequency of dosing and, potentially, compliance with therapy.[54] Elimination of NSAIDs largely depends on hepatic inactivation, with a small fraction of active drug being renally excreted. NSAIDs penetrate joint fluid, reaching approximately 60% of blood levels.

Efficacy

Prescription-strength NSAIDs are often prescribed for OA patients after treatment with acetaminophen proves ineffective or for patients with inflammatory OA. All NSAIDs and aspirin have similar analgesic and antiinflammatory effects, but these agents are only modestly more effective than acetaminophen.[60–62] In evaluating efficacy in OA studies, commonly used end points include pain on the visual analog scale (0 to 100) and the patient's global assessment of disease activity and functional status, using the Western Ontario and McMaster Universities Osteoarthritis Index questionnaire.[67] Effect size for NSAID treatment of OA is estimated at 0.32 (95% CI, 0.24-0.39) in comparison with that for acetaminophen at 0.21 (95% CI, 0.02-0.41). Because of differences among study designs and

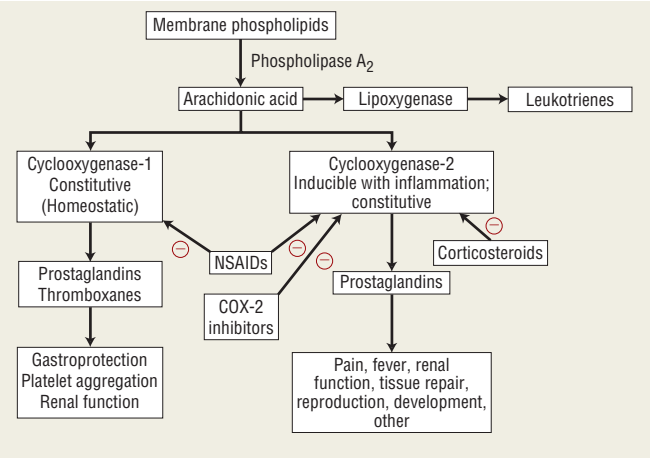

FIGURE 101-5. Pathway of synthesis for prostaglandins and leukotrienes. COX-1 and COX-2 are cyclooxygenase-1 and cyclooxygenase-2 enzymes, respectively. The minus (–) sign indicates inhibitory influence. Prostaglandins include PGE_2 and PGI_2; the latter is also known as prostacyclin.

patient populations, comparisons among efficacies of treatments are best made within the same study.

There is no definitive evidence to support superior efficacy for any NSAID.[60–62] However, individual patient response does differ among NSAIDs. The prescriber often relies on personal experience in choosing an NSAID. To assess efficacy in the individual patient, a trial that is adequate in time (2 to 3 weeks) and dose is needed. If the first trial fails, another NSAID in the same or another chemical class can be tried until an effective agent is found (see Table 101–2). Patients must understand this approach, appreciate the importance of adherence to medication therapy throughout this trial period, and actively participate in assessment of drug efficacy. Combining two NSAIDs increases adverse effects without providing additional benefit.

COX-2–selective inhibitors demonstrate similar analgesic benefits to traditional NSAIDs and to each other.[60–62] Celecoxib, lumiracoxib, and etoricoxib provided significant relief in OA compared with placebo and showed efficacy similar to other comparator NSAIDs. The newer COX-2–selective inhibitors have also been compared with older COX-2–selective inhibitors: Etoricoxib 30 mg/day and lumiracoxib 100 to 200 mg/day were similarly efficacious as celecoxib 200 mg/day and superior to placebo for OA.

Given that no proven efficacy differences exist among all traditional and COX-2–selective NSAIDs in OA, it is especially important that potential toxicities of these agents be rigorously examined. These safety issues are reviewed below.

Adverse Effects

Gastrointestinal Effects of Nonselective NSAIDs 8 The most common adverse effects of NSAIDs involve the GI tract, contributing to many treatment failures.[3,68–70] Minor complaints—nausea, dyspepsia, anorexia, abdominal pain, flatulence, and diarrhea—affect 10% to 60% of patients. To minimize these symptoms, NSAIDs should be taken with food or milk, except for enteric-coated products, which should *not* be taken with milk or antacids.

All NSAIDs have the potential to cause GI bleeding. [38,68] Un-ionized NSAIDs enter gastric mucosal cells, release hydrogen ions, and are concentrated ("ion trapped") within cells, resulting in cell death or damage. Gastric mucosal injury can also result from NSAID inhibition of gastroprotective prostaglandins.

The most common sites of GI injury are the gastric and duodenal mucosae. [68,69,71] The incidence of gastric ulcers with NSAID use is approximately 11% to 13%, and that for duodenal ulcers is 7% to 10%. Serious GI complications are associated with NSAIDs, including perforations, gastric outlet obstruction, and bleeding. These important GI complications occur in 1.5% to 4% of patients per year. NSAIDs are so widely used that these small percentages translate into substantial morbidity and mortality. Moreover, the risk increases to 9% per year for patients with the risk factors of advanced age, history of peptic ulcer or GI bleeding, or cardiovascular disease. Consequently, about 16,500 deaths and 103,000 hospitalizations in the United States are associated annually with NSAID use in rheumatoid arthritis or OA patients.[4] A recent review that included a total of 1.3 million patients taking traditional NSAIDS for at least 2 months showed that 1 in 5 developed endoscopically evident ulcers, 1 in 70 had ulcer symptoms, 1 in 150 developed a GI tract perforation, and 1 in 1,200 died.[38]

A key part of the clinician's decision regarding starting NSAID therapy for an OA patient is the patient's risk for GI toxicity. [3,68–71] Increased GI risk is seen for those with a history of complicated ulcer [relative risk (RR) 13.5], use of multiple NSAIDs, including aspirin (RR = 9), use of high-dose NSAID (RR = 7), use of anticoagulant (RR = 6.4), age older than 70 years (RR = 5.6), and concomitant use of corticosteroids (RR = 2.2).[38]

Medications are available for the treatment or prevention of ulcers in high-risk patients. [32,69,70,72] Misoprostol protects against both gastric and duodenal NSAID-induced ulcers, and more importantly, their associated serious GI complications (perforations, gastric outlet obstruction, and bleeding). Unfortunately, misoprostol frequently causes diarrhea and abdominal cramps. Because of its abortifacient properties, misoprostol is contraindicated in pregnancy and in women of childbearing age who are not maintaining adequate contraception. It must be dispensed in its original container, which carries a warning for these individuals. Misoprostol is also available in a combination product with diclofenac, which bears the same restrictions as misoprostol alone.

Other agents have been evaluated in attempts to prevent NSAID-induced gastropathy. PPIs are effective, although neither sucralfate or H_2 antagonists have been shown to be protective.

Recently, Canadian consensus guidelines were developed to recommend gastroprotection for those on NSAID therapy.[70] The multidisciplinary group focused on four areas: Benefits of traditional NSAIDs, aspirin, and COX-2 inhibitors; harms of traditional NSAIDs, aspirin, and COX-2 inhibitors; reducing harms of traditional NSAIDs, aspirin, and COX-2 inhibitors; and economic considerations. Recommendations were made for patients at low GI and cardiovascular risk, low GI risk and high cardiovascular risk, high GI risk and low cardiovascular risk, and for those with high GI and cardiovascular risk (Fig. 101–6).

Gastrointestinal Effects of COX-2–Selective Inhibitors Celecoxib, rofecoxib, and all COX-2–selective inhibitors studied to date have demonstrated fewer endoscopically observed ulcers compared with traditional NSAIDs. Such ulcers are relatively common with NSAIDs and are often asymptomatic. Data regarding the rare but serious GI complications of perforation, obstruction, or bleeding are more difficult to obtain as very large numbers of patients are required for such studies.

In the Celecoxib Long-Term Arthritis Safety Study (CLASS) study, there was a reduced risk of ulcer complications and symptomatic ulcers for 400 mg daily celecoxib compared with nonselective NSAID combined at the 6-month point but not at one year. Celecoxib also did not decrease the risk of ulcer complications alone (perforation, obstruction, bleeding), and there was no gastroprotection by celecoxib in those taking aspirin. In the Successive Celecoxib Efficacy and Safety Study I (SUCCESS-I), however, celecoxib significantly reduced the risk of GI complications and of combined GI complications and symptomatic ulcers over 12 weeks, in comparison with nonselective NSAIDs.[73] Celecoxib did not reduce GI events in those taking aspirin.

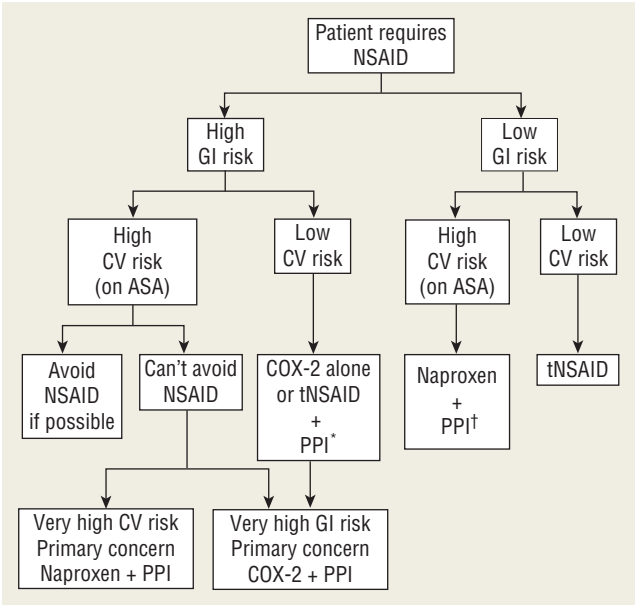

FIGURE 101-6. Algorithm for the use of long-term NSAID therapy and gastroprotective agents according to a patient's gastrointestinal and cardiovascular risk. *In high-risk patients, a COX-2 inhibitor and a tNSAID plus proton pump inhibitor (PPI) show similar reductions of rebleeding rates, but these reductions may be incomplete. †In general, most patients on acetylsalicylic acid plus naproxen would need the addition of a PPI. However, for some patients at very low GI risk, naproxen alone may be appropriate. *(Rostom A, Moayyedi P, Hunt R; Canadian Association of Gastroenterology Consensus Group. Canadian consensus guidelines on long-term nonsteroidal anti-inflammatory drug therapy and the need for gastroprotection: benefits versus risks. Aliment Pharmacol Ther. 2009 Mar 1;29(5):481. Wiley-Blackwell Publishers.)*

A systematic review of eight studies, three of which focused on celecoxib, demonstrated a 58% reduced risk for celecoxib compared with nonselective NSAID for ulcer complications and a 59% reduced risk for celecoxib compared with nonselective NSAID for ulcer complications combined with symptomatic ulcers.[60] Celecoxib use was also found to have significantly fewer GI symptoms of dyspepsia, nausea, diarrhea, and abdominal pain). Celecoxib users did have a modest (26%) but significant increased risk of "GI symptoms" compared with placebo.[73]

In addition and in celecoxib's favor, its use was associated with decreased outpatient physician claims for upper GI symptoms compared with other prescription nonspecific NSAIDs. Celecoxib was also comparable to a combination of diclofenac and omeprazole in reducing the risk of recurrent GI bleeding for patients who had a prior GI bleed.[74] Celecoxib remains on the market and is an alternative to traditional NSAIDs for those at high risk for GI toxicity.

GI safety for rofecoxib was evaluated in the Vioxx Gastrointestinal Outcomes Research (VIGOR) study, where patients were randomized to receive rofecoxib 50 mg daily or naproxen 500 mg twice daily; use of concomitant aspirin was prohibited. Those randomized to rofecoxib experienced a 50% lower risk of serious GI events.[75,76] These findings led to its approval by the FDA, but rofecoxib was withdrawn from the worldwide market in 2004 because of increased risk of cardiovascular events, as discussed in the section on cardiovascular risk.[76]

Lumiracoxib was evaluated in the Therapeutic Arthritis Research and Gastrointestinal Event Trial (TARGET).[77] With lumiracoxib, there was a significant 66% reduction in the risk of ulcer complications (perforation, gastric outlet obstruction, bleeding) compared with naproxen. However, in those taking aspirin, there was no protective effect of lumiracoxib. As mentioned earlier, lumiracoxib did not receive FDA approval but has been widely marketed in other countries. It has been withdrawn from the market in the United Kingdom and Australia due to safety concerns.

Etoricoxib was evaluated in the Multinational Etoricoxib and Diclofenac Arthritis Long-Term Program (MEDAL) study, in which etoricoxib 60 to 90 mg/day was compared with diclofenac 150 mg/day.[78] With etoricoxib, the risk of *clinical* GI events (perforation, gastric outlet obstruction, bleeding, and ulcers combined) was significantly reduced compared with diclofenac. However, there was no advantage for etoricoxib when complicated GI events alone (perforation, gastric outlet obstruction, bleeding) were evaluated. Etoricoxib is widely marketed in other countries. However, the FDA indicated that a favorable risk-to-benefit ratio had not been demonstrated, and the FDA did not approve the drug.

In summary, there is evidence that COX-2 inhibitors pose a decreased risk of GI toxicity compared with nonspecific NSAIDs. Proof that all COX-2 inhibitors are equally GI safe is lacking; this may reflect intrinsic differences among agents, result from differences in study design, patient population, or concomitant medication use. All COX-2–selective inhibitors decrease the risk of endoscopic ulcers and reduce GI symptoms such as dyspepsia and nausea. Celecoxib decreased the risk of ulcer complications as well as symptomatic ulcers. Lumiracoxib also reduced the risk ulcer complications as well as symptomatic ulcers. Etoricoxib did reduce clinical GI events, but it was not proven to decrease the risk of ulcer complications. No COX-2–selective inhibitor has been proven to reduce the risk of ulcer complications for those patients taking aspirin. This is an important limitation because many of the same patients who are in need of OA pain relief also need cardioprotective aspirin.

Finally, aside from using a COX-2 inhibitor or using a nonspecific NSAID with a PPI for gastroprotection, the combination of celecoxib with a PPI has also been studied. For patients at very high GI risk, who had experienced a prior GI bleed, the combination of a PPI with celecoxib substantially decreased the risk of future bleeding ulcers compared with celecoxib alone.[74]

Cardiovascular Risk of COX-2 Inhibitors and Traditional NSAIDs In 2004, rofecoxib was withdrawn from the market after analysis of the Adenomatous Polyp Prevention on Vioxx (APPROVe) trial, where rofecoxib doubled the risk of cardiovascular events compared with placebo.[76] Celecoxib use in the Adenoma Prevention with Celecoxib (APC) trial also increased cardiovascular risk.[79] These observations raised questions about the cardiovascular safety of all COX-2–selective NSAIDs and even traditional NSAIDs. The FDA formulated regulations and new labeling on all NSAIDs, and these events prompted metaanalyses of randomized controlled trials of COX-2–selective inhibitors and of NSAIDs.[80–83] Case control and cohort studies of patients using these agents have also examined cardiovascular risks involved with their use.[81,82]

The increased cardiovascular risk posed by rofecoxib was clearly demonstrated in the APPROVe trial, and the VIGOR trial also showed this risk.[38] The cardiovascular risk of celecoxib, particularly when used at the approved dose for OA (200 mg daily) is much less certain. In the CLASS study, a small but insignificant increase risk in cardiovascular risk was shown at a dose of 400 mg/day, and the APC trial showed a significantly increased risk with a dose greater than 400 mg/day. However, the Alzheimer Disease Antiinflammatory Prevention Trial (ADAPT) study, using 200 mg twice daily, did not show increased cardiovascular risk.[82]

The cardiovascular safety of lumiracoxib was evaluated in the TARGET study.[77] Cardiovascular risk with lumiracoxib showed a nonsignificant increase relative to ibuprofen, but not in comparison to naproxen, and this increase was only seen in those not taking aspirin. The cardiovascular safety of etoricoxib was evaluated in the MEDAL study.[80] Etoricoxib (60 or 90 mg daily) and diclofenac (150 mg daily) were compared, and very similar event rates for

thrombotic cardiovascular events occurred for the etoricoxib group and for the diclofenac group. Both studies had drawbacks. TARGET had few events (50 and 59 in the two groups). For the MEDAL study, diclofenac was not an ideal comparator to show that etoricoxib had no increased risk relative to nonselective NSAIDs, as it also possessed come COX-2 activity.

Other studies on coxibs including cardiovascular events and a metaanalysis of 138 randomized controlled trials including 145,373 patients were carried out.[81] Studies were analyzed for MI, stroke, or cardiovascular death, as well as a combined end point for all three ("cardiovascular events"). Coxibs as a whole, compared with placebo, increased the risk for cardiovascular events, RR of 1.42 (1.13-1.78). There was no increased risk for strokes alone, and increased risk was primarily due to myocardial infarction (MI), with a RR of 1.86 (1.33-2.59). This increased risk was spread across the class of COX-2–selective inhibitors, but most information came from trials of celecoxib and rofecoxib. For celecoxib, there was a significant trend for increased cardiovascular risk with higher daily doses (at or above 400 mg/day). In comparing coxibs with traditional NSAIDs, coxibs were associated with significantly more cardiovascular events than naproxen, RR = 1.57 (1.21–2.03), again primarily due to MIs, RR = 2.04 (1.41–2.96).

The same work also included metaanalyses of NSAIDs compared with placebo. Traditional NSAIDs showed increased cardiovascular events with diclofenac [RR = 1.63 (1.12-2.37)] and an insignificant increase with ibuprofen [RR = 1.51 (0.96-2.37)], but no increased risk with naproxen. A drawback in this work was that with the number of cardiovascular events in the metaanalyses, it was not possible to statistically differentiate the risk of one coxib compared with another. However, no heterogeneity was seen among the coxibs studied, which suggests a class effect.

Further insights into the cardiovascular risk of celecoxib was obtained from a pooled analysis of 7,950 patients in six placebo-controlled trials using three dose regimens of celecoxib (Cross Trial Safety Analysis).[82] Although the analysis was limited to conditions other than arthritis, it provides insight on the relationship between celecoxib dose and events and the importance of underlying cardiovascular risk. For the composite end point of cardiovascular death, MI, stroke, heart failure, or thromboembolic events, for all dose regimens, the overall hazard ratio for celecoxib compared with placebo was 1.6 (95% CI, 1.1-2.3). The hazard ratios with different doses were 3.1 (95% CI, 1.5-6.1) for 400 mg twice daily, 1.8 (95% CI, 1.1-3.1) for the 200 mg twice daily dosing, and the lowest risk, 1.1 (95% CI, 0.6-2.0) for 400 mg once daily dosing. In the study, patients were also stratified at baseline into three cardiovascular risk groups. The overall event rate increased when comparing the groups with low, intermediate, and highest baseline risk. When adjusted for baseline cardiovascular risk, there was a highly significant trend for increased risk, again increasing with dose. The adverse effect of dose was highest in those classified as high risk at baseline. Whether patients used or did not aspirin, celecoxib was associated with increased risk.

In addition to controlled trials, analysis of cohort or case control studies can also contribute to information about risk, but such studies have confounders and do not necessarily produce consistent findings. In a systematic review of observational studies of COX-2 inhibitors and traditional NSAIDs, including approximately 1 million patients, risk for cardiovascular events were calculated in comparison with nonusers or those with remote use of NSAIDs.[83] The summary RR was 1.33 (95% CI, 1.00-1.79) for rofecoxib 25 mg/day and 2.19 (95% CI, 1.64 to 2.91) with more than 25 mg/day, with risk apparent within the first month of treatment. Celecoxib summary RR was 1.06 (95% CI, 0.91-1.23), but there was much variation in risk among studies. Other summary RRs examined were for naproxen at 0.97 (95% CI, 0.87-1.07), piroxicam at 1.06 (95% CI, 0.70-1.59), and ibuprofen at 1.07 (95% CI, 0.97-1.18). Diclofenac, however, showed an increased summary RR of 1.40 (CI, 1.16-1.70), which is concerning.[83]

Taken together, the above data, both from controlled trials and from observational studies, confirm the increased cardiovascular risk seen with rofecoxib. Celecoxib 200 mg/day or even 400 mg/day does not appear to increase risk, but cardiovascular risk is likely increased with doses above 400 mg/day. In addition, , the risk of taking higher doses of celecoxib is greater for those with high cardiovascular risk than for those with low cardiovascular risk. Although studies with lumiracoxib and etoricoxib are somewhat reassuring and do not point to substantially increased cardiovascular risk, further work is needed on this issue. The balance of the evidence also suggests that, for the traditional NSAIDs that have been examined, with the exception of diclofenac, there is no significant or substantial increase in risk.

These differences may depend on the degree of selectivity of specific COX-2 inhibitors for COX-2 versus COX-1 enzymes. COX-2 selectivity is relative: Some traditional NSAIDs, such as diclofenac, possess some COX-2 selectivity, and even among the formally labeled COX-2 inhibitors, COX-2 selectivity varies. Interestingly, rofecoxib is more COX-2 selective than celecoxib. It is possible that rofecoxib's greater selectivity is responsible both for better GI protection *and* for increased cardiovascular risk. Such a connection is plausible, given the effects of COX-1 and COX-2 enzymes on the formation of thromboxane A_2 and prostacyclin. A highly selective COX-2 inhibitor may tilt the balance in favor of thromboxane A_2, thus promoting platelet aggregation (beneficial for preventing GI bleeding, but posing a prothrombotic risk to the cardiovascular system).

Key issues for any future coxib development will be their degree of gastroprotection and what, if any, cardiovascular risk they pose. Further study will be needed to determine if one or more of these agents will be safe for the cardiovascular system and also gastroprotective, or whether the degree of gastroprotection is inextricably linked to the extent of cardiovascular risk for all COX-2–selective inhibitors.

CLINICAL CONTROVERSY

There is continuing controversy surrounding the clinically meaningful gastroprotective effects of COX-2 inhibitors and the cardiovascular risks they may pose. Are all COX-2 inhibitors GI protective? Do they all pose cardiovascular risk? Furthermore, while the gastrointestinal complications associated with traditional NSAIDs are well recognized, the cardiovascular risks posed by these agents are somewhat less clear. Some clinicians have applied the cardiovascular risk data regarding all NSAIDs (COX-1 and COX-2 selective) to practice with complete avoidance of all NSAIDs. Questions still remain regarding the relative safety of short courses of low-dose NSAIDs for cardiac patients with unrelieved OA pain.

Considerations for Patients at Risk for Both GI and Cardiovascular Events 9 Several American and international organizations have recommended strategies for NSAID use among patients at high risk for GI or cardiovascular events. Evidence-based Canadian consensus guidelines on long-term NSAID therapy, considering both GI and cardiovascular risk, were recently developed (Fig 101–7).[70] The recommendations presupposed use of cardioprotective aspirin in those with increased cardiovascular risk. For those without increased GI or cardiovascular risk, a nonspecific NSAID was recommended. For patients with low GI risk but high cardiovascular risk, naproxen may be safer than other NSAIDs. For those with increased GI risk but without increased cardiovascular risk, a COX-2–selective inhibitor, combined with a PPI, is probably

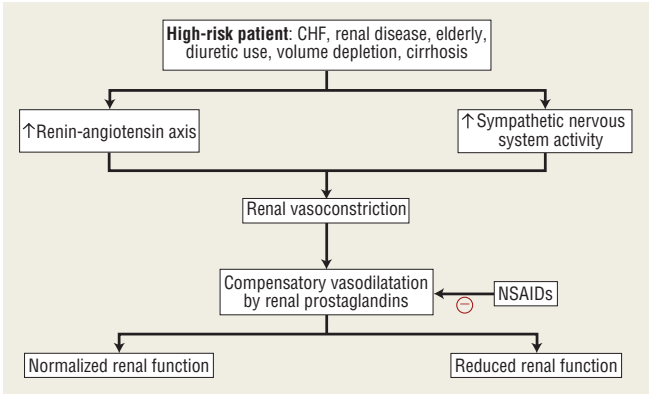

FIGURE 101-7. Mechanisms implicated in NSAID-induced renal injury. The minus (–) sign indicates inhibitory influence (CHF, congestive heart failure; NSAIDs, nonsteroidal antiinflammatory drugs).

safest from the GI perspective. For those patients who are at high GI and cardiovascular risk, careful consideration of which risk is most concerning is needed. If GI safety is paramount, a COX-2 inhibitor plus a PPI is recommended. If cardiovascular risk is the most concerning, naproxen plus a PPI would be preferred.

Other Toxicities Associated with NSAIDs 10 NSAIDs may cause kidney diseases, including acute renal insufficiency, tubulointerstitial nephropathy, hyperkalemia, and renal papillary necrosis.[84–86] Clinical features of these NSAID-induced renal syndromes include increased serum creatinine and blood urea nitrogen, hyperkalemia, elevated blood pressure, peripheral edema, and weight gain. Mechanisms of NSAID injury include direct toxicity and inhibition of local prostaglandins that promote vasodilation of renal blood vessels and preserve renal blood flow. Patients at high risk are those with conditions associated with decreased renal blood flow or taking certain medications. Examples are those with chronic renal insufficiency, congestive heart failure, severe hepatic disease, and nephrotic syndrome, those of advanced age, or those taking diuretics, angiotensin-converting enzyme inhibitors, cyclosporine, or aminoglycosides (Fig. 101–7).

Close monitoring is advisable for high-risk patients taking an NSAID, with monitoring of serum creatinine at baseline and within 3 to 7 days of drug initiation. For those with impaired renal function, the National Kidney Foundation recommends acetaminophen over NSAIDs, although acetaminophen may pose risks also, as discussed above.

Coxibs can also pose renal risks, and there is neither evidence nor rationale why this class of drugs would be safer than nonspecific NSAIDs. In a metaanalysis of randomized trials of NSAIDs including more than 100,000 patients, rofecoxib was shown to significantly increase risk of renal toxicity in comparison to placebo, celecoxib, and nonspecific NSAIDs.[86] Although rofecoxib is now off the market, this study provides an important caution as new coxibs are approved: Renal safety of coxibs may differ substantially. Keeping in mind that many OA patients may not be as healthy as trial participants, it is prudent to prescribe all coxibs and other NSAIDs with caution for patients who are at increased risk for renal dysfunction.

Coxibs and NSAIDs uncommonly cause drug-induced hepatitis; the two NSAIDs most frequently implicated are diclofenac and sulindac. Patient monitoring should include periodic liver enzymes (aspartate aminotransferase and alanine aminotransferase), with cessation of therapy if these values exceed two to three times the normal range. In a pooled analysis of 41 studies including celecoxib, there was a low rate of serious, hepatic-related adverse events with celecoxib (1.11%), with no significant difference from naproxen or ibuprofen, but a significantly higher incidence with diclofenac (4.24%).[87]

Other toxic effects of NSAIDs include hypersensitivity reactions, rash, and CNS complaints of drowsiness, dizziness, headaches, depression, confusion, and tinnitus.[54] Although NSAIDs are generally avoided for patients with asthma who are aspirin-intolerant, studies indicate that celecoxib is well tolerated in aspirin-sensitive asthma, providing a viable option for these patients.[88] Celecoxib is a sulfonamide and is thus contraindicated for those with sulfa allergies. However, some patients with sulfa allergies have shown no reaction to celecoxib, and in a metaanalysis including more than 11,000 patients, allergic reactions for those who did have sulfonamide allergies were similar in those taking celecoxib compared with those taking other NSAIDs.

All nonspecific NSAIDs inhibit COX-1–dependent thromboxane production in platelets and thus increase bleeding risk. Importantly, aspirin inhibition is irreversible, and bleeding time requires 5 to 7 days to normalize after cessation of therapy, as new platelets enter the circulation. Other nonspecific NSAIDs inhibit thromboxane formation reversibly, with normalization of platelet function 1 to 3 days after the drug is stopped. The nonacetylated salicylate products and nabumetone, which have partial COX-2 selectivity, may be preferable to nonspecific NSAIDs.[54] COX-2–selective inhibitors do not block thromboxane synthesis and should pose even less bleeding risk. However, because warfarin and celecoxib are metabolized by the cytochrome P450 isoenzyme CYP2C9, patients receiving warfarin and COX-2 inhibitors should be followed closely.

Finally, NSAIDs should be used only with great caution and only if definitely necessary during pregnancy because of the risk to the fetus posed by the bleeding problems. In late pregnancy, all NSAIDs should be avoided because they may enhance premature closure of the ductus arteriosus. Many NSAIDs, including naproxen, diclofenac, and celecoxib have a pregnancy risk factor of C/D (third trimester), and ibuprofen is listed as category D throughout pregnancy. Acetaminophen has a pregnancy risk factor of B.

Drug–Drug and Drug–Food Interactions Important drug interactions with NSAIDs can be pharmacokinetic or pharmacodynamic in origin and have been reviewed.[54,89] The most potentially serious interactions include the use of NSAIDs with lithium, warfarin, other agents that increase bleeding risk, oral hypoglycemics, methotrexate, antihypertensives, angiotensin-converting enzyme inhibitors, β-blockers, and diuretics. Anticipation and careful monitoring often can prevent serious events when these drugs are used together. In addition, there are probable drug interactions with tacrolimus for ibuprofen, naproxen, diclofenac, and possibly other NSAIDs.

Another drug interaction has been noted for those taking some NSAIDs and cardioprotective doses of aspirin. Ibuprofen, used at doses of 400 mg or more, may block aspirin's antiplatelet effect if it is taken prior to aspirin. Patients are advised to take a single dose of ibuprofen at least 30 minutes after taking aspirin, or they should take their aspirin at least 8 hours after taking ibuprofen.[90] It is possible that other nonselective NSAIDs, such as naproxen, also may cause such interactions. Acetaminophen does not appear to interfere with the antiplatelet effect of aspirin.

Specific drug interactions are also seen with coxibs. Celecoxib metabolism is primarily via CYP2C9.[89] In clinical studies, increased celecoxib levels were seen with fluconazole administration. Cytochrome P450 inducers such as rifampin, carbamazepine, and phenytoin have the potential to reduce celecoxib levels. However, no clinically significant interactions have been documented with celecoxib and methotrexate, glyburide, ketoconazole, phenytoin, or tolbutamide. Because celecoxib inhibits CYP2D6, it has the potential to increase concentrations of a variety of agents, including antidepressants. Celecoxib increases lithium levels, as do other NSAIDs; thus, caution is needed when using coxibs or NSAIDs with lithium.

Dosing and Administration Administration of NSAIDs must be tailored to the individual patient with OA. For the OA patient who has failed an adequate trial of acetaminophen, trial with an NSAID is warranted, if no contraindications exist. Selection of an NSAID depends on the prescriber's experience, medication cost, patient preference, allergies, toxicities, and adherence issues. Individual patient response differs among NSAIDs (see Table 101–2), so if an inadequate response is obtained with one NSAID, another NSAID may yet provide benefit.[40,54,91]

Topical Therapies

11 Topical products can be used alone or in combination with oral analgesics or NSAIDs. Capsaicin, isolated from hot peppers, releases and ultimately depletes substance P from afferent nociceptive nerve fibers. Substance P has been implicated in the transmission of pain in arthritis, and capsaicin cream has been shown in four placebo-controlled studies to provide pain relief in OA when applied over affected joints.[40,92] Data comparing topical capsaicin to other effective pharmacologic treatments for OA is lacking.

Adverse events associated with capsaicin are primarily local, with one in three patients experiencing burning, stinging, and/or erythema that usually subsides with repeated application. Some patients may experience coughing associated with application. Capsaicin is a nonprescription product available as a cream, gel, or lotion in concentrations ranging from 0.025% to 0.075%.

To be effective, capsaicin must be used regularly, and it may take up to 2 weeks to take effect. Although use is recommended four times a day, a twice-daily application may enhance long-term adherence and still provide adequate pain relief.[92] Patients should be warned not to get the cream in their eyes or mouth and to wash their hands after application. When patients were queried using an electronic questionnaire that considered possible toxicities of treatments, as well as route of administration and cost, capsaicin was the most preferred by patients, even when it was portrayed as being less effective than NSAIDs.[55]

Topical NSAIDs can be used to achieve NSAID efficacy for the treatment of OA, while avoiding the serious adverse effects associated with systemic NSAID therapy. The mechanism of action of topical NSAIDs is thought to be primarily by local inhibition of COX-2 enzymes, although it is unclear if there are other factors that contribute to the beneficial effects of these agents. There tends to be high placebo response rates associated with topical therapy in general, as the act of rubbing itself may desensitize local nerve endings and activate pain-gating mechanisms, but active topical NSAID therapy is consistently superior to placebo.[93]

Topical NSAIDs are commonly associated with dermatologic adverse effects at the application site including pruritus, burning, pain, and rash with serious adverse events being rare. It is unclear if topical NSAIDs are associated with significant cardiovascular or gastrointestinal adverse events, although current data suggest relative safety. [94] Treatment with topical NSAIDs can be considered when first-line agents fail, are contraindicated, or are poorly tolerated. Recent treatment guidelines from the American Academy of Orthopedic Surgeons recommends topical NSAIDs as acceptable first-line therapy, although OARSI and ACR continue to recommend these agents as second line. [36,39,40]

The only FDA-approved topical NSAID for OA is diclofenac gel 1%. Other topical NSAIDs—including ibuprofen, ketoprofen, and indomethacin—are available as extemporaneously compounded products or as nonprescription products. It is important to note that many variables influence the extent and rate of absorption of topical drugs including the vehicle of the formulation, the molecular weight of the drug, and the hydrophilicity of the drug.[94] Care should be taken to choose a topical NSAID with a reliable delivery system.

Topical diclofenac 1% gel is applied four times daily using the dose measuring cards provided by the manufacturer. Patients should not exceed the recommended dose. Patients should avoid oral NSAIDs while using topical products to minimize potential for additive adverse effects. Care should be taken to avoid contact with the eyes or open wounds.

Although not well studied in a controlled setting, the use of topical rubefacients, containing methylsalicylate, trolamine salicylate, and other salicylates, may have modest, short-term efficacy in the treatment of acute pain associated with musculoskeletal conditions, including OA.[95] These agents act by providing topical counterirritation to the affected joint area rather than by local inhibition of COX-2 enzymes. Chronic OA pain may respond less favorably than acute pain. Clinically significant adverse events are local skin reactions that occur rarely. There are no reports of systemic toxicity associated with topical rubefacients.

Glucosamine and Chondroitin

Interest in chondroitin and glucosamine was spurred initially by anecdotal reports of benefit in animals and humans and by the ability of these substances to stimulate proteoglycan synthesis from articular cartilage in vitro. The excellent safety profile of these agents makes them especially appealing for use in those at high risk for adverse events, such as elderly patients, and in those with multiple morbidities. Over the last several years, enthusiasm for these agents has waned as additional data has become available to the point that two recent evidence-based guidelines recommend against the use of glucosamine and chondroitin for the treatment of knee OA.[39,96]

Numerous trials have been conducted with suboptimal study designs, and this has led to a variable response to glucosamine and/or chondroitin.[96] Study design flaws have included small sample size, wide intersubject heterogeneity, industry sponsorship, lack of clinically important end points, as well as lack of data related to intention-to-treat analysis. Conducting a metaanalysis of these type glucosamine and chondroitin trials does not necessarily solve the initial trial design issues. In contrast to the early reports of suboptimally designed studies, a large, well-controlled National Institutes of Health–sponsored study demonstrated no significant clinical response to glucosamine therapy alone, chondroitin therapy alone, or combination glucosamine–chondroitin therapy when compared with placebo across all patients.[97] This trial provides the highest quality evidence available on the efficacy of glucosamine and chondroitin to date. However, subgroup analyses for patients with moderate to severe knee pain showed a response to combination glucosamine–chondroitin therapy superior to placebo, although this finding did not reach the predetermined threshold for pain reduction. The safety of the glucosamine and chondroitin therapy was similar to that of placebo.

The exact role of glucosamine, chondroitin, or a combination of the two products is still unclear. Because of the relative safety of these agents, many clinicians consider a trial of glucosamine–chondroitin reasonable for patients with moderate to severe knee OA considering the adverse effects associated with traditional OA treatments. Dosing should be at least 1,500 mg/day of glucosamine and 1,200 mg/day of chondroitin. The glucosamine component should be the sulfate salt rather than the hydrochloride salt, as nearly all positive efficacy studies used the better-absorbed sulfate salt. Glucosamine-related adverse events are generally mild and include gastrointestinal symptoms (gas, bloating, cramps). If made from shellfish, however, glucosamine should not be used for patients with shellfish allergies. The initial concerns regarding glucosamine-induced hyperglycemia had likely been overstated since later safety data in both healthy subjects and those with type 2 diabetes mellitus

did not show significant elevations in blood glucose. Chondroitin is extremely well tolerated with the most common adverse effect being nausea. Depending on the source of chondroitin (cattle, pig, or shark), this compound could also pose risk to persons who are allergic to shark.

Because glucosamine and chondroitin are marketed in the United States as dietary supplements, neither the products nor their purity is adequately regulated by the FDA. The potential consequences related to the lack of regulatory oversight for these products can affect both efficacy and safety. Products containing less than labeled doses can compromise efficacy, while those containing ingredients not included on the labeling can compromise safety. A variety of brand name and generic products are available.

CLINICAL CONTROVERSY

The role of herbal and supplement therapies in the treatment of OA is a source of continuing controversy. A variety of herbal therapies—including ginger, devil's claw, methylsulfonylmethane, flavonoids, willow bark, fish oils, avocado/soybean unsaponifiables, and *Boswellia serrata*—have been purported to have efficacy in the treatment of pain associated with OA. Many patients encounter advertising and other publications in the lay media extolling the benefits of these products. Unfortunately, the lack of scientific trials evaluating these agents makes it difficult to determine their role in therapy. Until additional efficacy and safety information becomes available, recommendations regarding the routine use of these products should be tempered by known drug safety data (if available) and other related safety issues. Costs of therapy, delays in seeking treatments known to be effective, and potential exposure to products produced without standard manufacturing processes can also lead to poor outcomes for patients.

Corticosteroids

Intraarticular glucocorticoid injections can provide excellent pain relief, particularly when a joint effusion is present.[40,98] Aspiration of the effusion and injection of glucocorticoid are carried out aseptically, with examination of the aspirate recommended to exclude crystalline arthritis or infection. (This incidence is low, however—approximately 1 in 50,000 procedures.) After injection, the patient should minimize activity and stress on the joint for several days. Initial pain relief may be seen within 24 to 72 hours after injection, with peak pain relief about 7 to 10 days after injection and lasting up to 4 to 8 weeks.

Several randomized, placebo-controlled, double-blind studies have shown that intraarticular corticosteroids are superior to placebo in alleviating knee pain and stiffness caused by OA.[98] The branched esters of triamcinolone and methylprednisolone are preferred by practitioners because of the reduced solubility that allows the agents to remain in the joint space longer. There is no evidence of a clinically superior corticosteroid for intraarticular use, with equipotent doses of methylprednisolone acetate and triamcinolone hexacetonide having similar efficacy.[99] Average doses for injection of large joints in adults are 10 to 20 mg of triamcinolone hexacetonide or 20 to 40 mg of methylprednisolone acetate. This therapy is generally limited to three or four injections per year due to the potential systemic effects of corticosteroids and because the need for more frequent injections indicates little response to the therapy.

Adverse events associated with intraarticular injection of corticosteroids can be local or systemic in nature. Systemic adverse events are the same as with any other systemic corticosteroid and can include hyperglycemia, edema, elevated blood pressure, dyspepsia, and, rarely, adrenal suppression with continuous, repeated injections. Hyperglycemia may occur in patients with stable diabetes mellitus as well as those without history of abnormal glycemic control.[39] Local adverse effects can include infection in the affected joint, osteonecrosis, tendon rupture, and skin atrophy at the injection site. It has long been thought that intraarticular corticosteroids can hasten cartilage loss, but the potential risk of cartilage destruction with steroid injections has not been substantiated. The rate of cartilage loss tends to be similar between treated and control groups.

Systemic corticosteroid therapy is not recommended in OA, given the lack of proven benefit and the well-known adverse effects with long-term use.

Hyaluronate Injections

Agents containing hyaluronic acid (HA; sodium hyaluronate) are available for intraarticular injection for treatment of knee OA.[100] High-molecular-weight HA is an important constituent of synovial fluid. Endogenous HA may also have antiinflammatory effects. Because the concentration and molecular size of synovial HA decreases in OA, administration of exogenous HA products have been studied, with the theory that this could reconstitute synovial fluid and reduce symptoms. In fact, HA injections temporarily and modestly increase viscosity. HA injections appear to have positive effects on pain and function compared with placebo, although most studies were short term and poorly controlled, and placebo injections also reduced OA pain dramatically. When evaluating pain score improvements, it is essential to determine if score improvement corresponds to clinically meaningful improvement for patients. Extensive evaluation of the literature has revealed potential publication bias of HA studies including bias related to high levels of industry sponsorship as well as a substantial number of studies with unpublished data. [96] Most HA products are injected once weekly for either 3 or 5 weeks, depending on the specific agent administered. There are six commercially available preparations: Hyalgan, Euflexxa (20 mg sodium hylaronate/2 mL), Supartz (25 mg sodium hylaronate/2.5 mL), Synvisc (16 mg hylan polymers/ 2 mL), Synvisc-One (48 mg hylan polymers/6 mL), and Orthovisc (30 mg hyaluronan/2 mL). Hyalgan and Supartz are administered weekly for five injections, whereas Synvisc, Euflexxa, and Orthovisc are administered weekly for three injections. Synvisc-One is administered as single one time dose with efficacy up to 26 weeks. Injections are generally well tolerated, although acute joint swelling, effusion, and stiffness can occur as well as local skin reactions, including rash, ecchymoses and pruritus have been reported. Rarely, systemic adverse events including hypersensitivity reactions have occurred.

HA injections may be beneficial for patients with knee OA unresponsive to other therapies. HA products have not been shown to benefit patients with hip OA.[101] These agents are expensive because the treatment includes both drug costs and administration costs. As a result, HA injections are often used after more effective and less expensive therapies have demonstrated a lack of efficacy.

Opioid Analgesics

Low-dose opioid analgesics can be useful for patients who experience no pain relief with acetaminophen, NSAIDs, intraarticular injections, or topical therapy. For patients with underlying diseases that limit the use of nonopioid analgesics, opioid analgesics can effectively relieve pain. A common clinical scenario may include the patient who cannot take NSAIDs because of renal failure or cardiovascular disease. Patients in whom all other treatment options have failed and who are at high surgical risk, precluding joint arthroplasty are also candidates for opioid therapy. As many

patients with OA are elderly, it is important to carefully use opioids to promote safety. The following recommendations have been suggested to optimize opioid therapy: (1) use the least invasive route of administration, (2) initiate one agent at a time, at a low dose, (3) allow a sufficiently long interval between dose increases to allow an assessment of efficacy and safety, (4) use a long-acting preparation, (5) therapy should be constantly monitored and adjusted if necessary, (6) changing opioids may be necessary.[102]

Sustained-release (SR) compounds usually offer better pain control throughout the day, and are used when immediate-release (IR) opioids do not provide a sufficient duration of pain control. A variety of immediate and sustained-release opioid compounds have been studied including oxycodone IR and SR, morphine IR and SR, hydromorphone and fentanyl transdermal patch.[102]

Adverse effects are common in opioid-treated OA patients. More than 75% of patients in clinical trials experience at least one typical opioid-related (nausea, somnolence, constipation, and dizziness) adverse effect. Although this is not an unexpected finding, it serves as a reminder to use opioids cautiously in elderly patients who may be more susceptible to adverse effects.

If pain is intolerable and limits activities of daily living, and the patient has sufficiently good cardiopulmonary health to undergo major surgery, joint replacement may be preferable to continued reliance on opioids.

Tramadol

Tramadol, an analgesic with affinity for the μ-opioid receptor, as well as weak inhibition of the reuptake of norepinephrine and serotonin neurotransmitter has modest analgesic effects (with or without acetaminophen) for patients with OA when compared with placebo.[103] Tramadol is also modestly effective as add-on therapy for patients taking concomitant NSAIDs or COX-2–selective inhibitors.[104] As with opioid analgesics, tramadol may be helpful for patients who cannot take NSAIDs or COX-2–selective inhibitors. Tramadol should be initiated at a lower dose (100 mg per day) and may be titrated as needed for pain control to a dose of 200 mg per day. Tramadol is available in a combination tablet with acetaminophen and as a sustained-release tablet.

Opioid-like adverse effects such as nausea, vomiting, dizziness, constipation, headache, and somnolence are common with tramadol. These occur in 60% to 70% of treated patients, and 40% discontinue tramadol because of an adverse effect.[103] Although the frequency of adverse effects is high, the severity of adverse effects is less than with NSAIDs, as tramadol use is not associated with life-threatening gastrointestinal bleeding or renal failure.

Considerations for Future Therapeutic Options

Strategies aimed at expanding therapeutic options are concentrated on an array of disease-modifying drugs targeted at preventing, retarding, or reversing damage to articular cartilage. Thus far, OA is a progressive disease that can only be treated symptomatically. Because of this, clinicians are very interested in nonpharmacologic measures and pharmacologic therapy that can slow the progression of damage to the articular cartilage. Current approaches to slow progression of OA are directed at 3 different tissue specific targets: (1) cartilage, (2) synovial membrane, and (3) subchondral bone. One modality being explored in the preclinical stage is that of autologous chondrocyte transplantation (ACT) using mesenchymal stem cells, a treatment aimed at restoring cartilage lost or damaged by OA.

Therapies directed at preserving cartilage include enzyme inhibitors of MMPs, inhibitors of inducible nitric oxide synthase, inhibitors of eicosanoids, and nerve growth factor inhibitors.[105] Several of these investigational agents have progressed from testing in animal models to clinical trials in humans. Doxycycline, as a tissue inhibitor of metalloproteinases potentially decreases cartilage destruction. In knee OA, doxycycline has been shown to delay loss of articular cartilage (joint space narrowing) in humans when compared with placebo.[106] Ongoing phase III clinical trials with licofelone, a lipoxygenase/cyclooxygenase inhibitor (LOX/COX) have demonstrated some encouraging preliminary data in delaying progression of OA.[107] Combined LOX/COX inhibitor may decrease the production of proinflammatory leukotrienes associated with the progression of OA. An agent targeted toward maintaining synovial membrane integrity is diacerein, an interleukin-1β inhibitor. In a metaanalysis including a total of 2,069 OA patients, this agent decreased pain to a modest but statistically significant extent compared with placebo. In long-term studies, diacerein appeared to show a significant slowing of progression of joint space narrowing at the hip, but not at the knee.[108]

Slowing the progression of OA may also be achieved by attempts to modify or repair bony changes associated with OA. Current strategies being evaluated in humans include the use of bisphosphonates, calcitonin, selective estrogen receptor modulators, parathyroid hormone, strontium, and MMP-13 inhibitors. The definitive role of these agents in modifying bone resorption as a strategy to delay the progression of bone damage associated with OA is yet to be determined. Aside from agents that may prevent disease progression, attempts to find new agents or methods to treat symptoms of OA are being made. There is recent interest in the potential of COX-inhibiting nitric oxide-donor compounds (CINODs) to relieve OA pain while sparing GI adverse effects.[45,109] Published clinical data on the CINOD, Naproxinod, has shown that it provided some improvement in GI tolerance, and was similarly efficacious as naproxen for pain control in OA patients. naproxinod may also have advantages with regard to blood pressure, as it provided a small decrease in blood pressure of treated subjects, whereas comparator NSAIDs caused a small increase in blood pressure. Another agent being studied is avocado/soy unsaponifiables (ASUs). A recent metaanalysis including a total of 664 participants with knee or hip OA showed that subjects randomized to ASU demonstrated a modest but significant improvement in pain.[45] It is theorized that the oily fractions of avocado unsaponifiables decrease production of nitric oxide and stimulate production of plasminogen activator inhibitor-1 that can decrease MMPs.

In addition to pharmacologic agents, acupuncture has been examined in OA. In a systematic analysis of 18 randomized, controlled trials of manual or electroacupuncture, 10 showed positive effects for acupuncture.[110] However, in a recent, large, randomized, and well-controlled study, acupuncture was not seen to be any more effective than sham controls.[111]

PHARMACOECONOMIC CONSIDERATIONS

There are substantial economic ramifications with OA, as the disease is extremely common, and OA ranks second in causes of disability in the United States.[1,40]

One of the highest costs associated with the pharmacotherapy of OA is hospitalization for treatment of NSAID-related complications, particularly serious GI adverse events. Several cost analysis have been performed to determine the cost-effectiveness of gastroprotective therapy in NSAID users. The cost-effectiveness of using NSAIDS or COX-2–selective inhibitors with or without concomitant PPI therapy in both high-risk and low-risk patients was reported, based on estimates of the risk of GI complications in these settings.[112] The cost of avoiding one serious GI complication would be $61,933 if all NSAID patients were given a PPI, but only $4,355 if PPIs were limited to high-risk patients. In the same analysis, the cost of avoiding one serious GI complication would be $62,467 if

all NSAID patients were given a COX-2–selective inhibitor. The cost-effectiveness of an NSAID plus a PPI for high-risk patients has been demonstrated by others as well.[113] Historically, gastroprotective therapy or the use of COX-2–selective inhibitors for low-risk patients has not been cost-effective because of the large number needed to treat to prevent serious events, but current data suggest that concomitant PPI therapy in low-risk patients is cost-effective if the agent selected is a generic, multisource product. [114] The use of COX-2–selective inhibitors to protect gastric mucosa in aspirin users is not cost-effective, because aspirin negates most, if not all, of the gastroprotective effects of these agents.[112,113]

Pharmacoeconomic considerations for OA involve the selection of therapy for the initial treatment of patients with OA. Use of the nonprescription analgesic acetaminophen as initial therapy has greatly reduced medication costs in comparison with the use of NSAIDs, many of which are by prescription only. NSAID costs range from $20 to $150 per month, depending on the medication, daily dose, and regimen selected. As NSAIDs as a class are therapeutically similar, use of less-expensive NSAIDs, such as nonprescription ibuprofen or naproxen or a multisource generic product, may minimize the cost of medicine to the patient. More-expensive NSAIDs can be prescribed if neither of these offers benefit after a 2-week trial at sufficient doses.

Nearly all elderly patients are eligible for prescription drug coverage through Medicare Part D insurance programs or other private insurance to assist with the costs of prescription medications for the treatment of OA. The use of nonformulary or noncovered medications can significantly increase patient drug costs. Careful attention to selection of appropriately covered medications will increase the affordability of medication for patients receiving drug therapy for OA.

EVALUATION OF THERAPEUTIC OUTCOMES

Pharmacotherapy monitoring in OA is patient specific. It should be guided by aspects of disease that are most troubling to the patient, such as pain or decreased function, as well as the patient's risk of adverse effects. To monitor efficacy, the patient's baseline pain can be assessed with a visual analog scale, and range of motion for affected joints can be assessed, providing baseline measures to monitor the success of therapy. Baseline radiographs are helpful to document the extent of joint involvement and to follow progression of disease with therapy. Additional tests of OA severity may include measurement of grip strength, 50 ft (15.2 m) walking time, patient and physician global assessment of OA severity, and the Western Ontario and McMaster Universities Arthrosis Index or Stanford Health Assessment Questionnaire to monitor ability to perform activities of daily living. A decrease in the use of analgesics or NSAIDs would suggest a beneficial effect of nonpharmacologic interventions. Lastly, disease-specific quality of life is valuable in assessing clinical response to interventions.

Adverse events with acetaminophen are uncommon. NSAID toxicity is more problematic and requires continued individual attention to minimize serious consequences from this drug therapy option. Each patient's gastrointestinal, cardiovascular, renal, and other risks, as well as age and comorbidities, should be assessed. When assessing toxicity of therapy, patients should be asked first if they are having any "problems" with their medications. This open-ended question can be followed with direct questions relating to the most common adverse effects associated with the respective medication. Symptoms of abdominal pain, heartburn, nausea, or change in stool color provide valuable clues to the presence of GI complications, although serious GI complications can occur without warning. Patients also should be monitored for the development of hypertension, weight gain, edema, skin rash, and CNS adverse effects such as headaches and drowsiness. Baseline serum creatinine, complete blood count, and serum transaminases are repeated at 6- to 12-month intervals to identify GI, renal, and hepatic toxicities.

For patients receiving intraarticular corticosteroids, improvement should begin with 2 to 3 days and last 4 to 8 weeks. Patients should be advised about possible injection site reactions, as well as possible systemic effects, especially for those with hypertension or diabetes, as there is a potential for increased blood pressure or blood glucose. Modest improvement with the use of intraarticular HA can begin within 3 to 4 weeks and can last several months, and patients should be advised about possible injection-site reactions and allergic reactions.

For patients receiving opioids or tramadol, relief from pain is expected to occur rapidly. Patients, especially if frail or elderly, should be monitored carefully and cautioned about sedation, dysphoria, nausea, risk of falls, and constipation. Additional monitoring should include strategies to assess development of opioid tolerance and addiction.

CONCLUSIONS

OA is a very common, slowly progressive disorder that affects diarthrodial joints and is characterized by progressive deterioration of articular cartilage, subchondral sclerosis, and osteophyte production. Clinical manifestations include gradual onset of joint pain, stiffness, and limitation of motion. The primary treatment goals are to reduce pain, maintain function, and prevent further destruction. An individualized approach based on education, rest, exercise, weight loss as needed, and analgesic medication can succeed in meeting these goals. Recommended drug treatment starts with acetaminophen ≤4 g/day and topical analgesics as needed. If acetaminophen is ineffective, NSAIDs may be used, often providing satisfactory relief of pain and stiffness. Individuals at increased risk for toxicity from NSAIDs, especially for GI, cardiovascular, or renal events, deserve special attention. Coxibs may have advantages in some OA patients, but their safety relative to other NSAIDS and their role in OA remain in a state of flux. Glucosamine–chondroitin may be useful in moderate to severe arthritis and is safe. Experimental therapy aimed at preventing the progression of OA requires further clinical investigation before entering widespread clinical use.

CHAPTER 102

Gout and Hyperuricemia

MICHAEL E. ERNST AND ELIZABETH C. CLARK

KEY CONCEPTS

1. In the absence of a history of gout, asymptomatic hyperuricemia does not require treatment.
2. Acute gouty arthritis may be treated effectively with short courses of high-dose nonacetylated nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, or colchicine.
3. Colchicine is highly effective at relieving acute attacks of gout but has the lowest benefit-to-toxicity ratio of the available pharmacotherapy for gout.
4. Uric acid nephrolithiasis should be treated with adequate hydration (2 to 3 L/day), a daytime urine-alkalinizing agent, and 60 to 80 mEq/day (60 to 80 mmol/L) of potassium bicarbonate or potassium citrate.
5. Treatment with urate-lowering drugs to reduce risk of recurrent attacks of gouty arthritis is considered cost-effective for patients having two or more attacks of gout per year.
6. Xanthine oxidase inhibitors are efficacious for the prophylaxis of recurrent gout attacks in both underexcreters and overproducers of uric acid. Allopurinol should be started with a low dose (100 mg/day) after the acute attack has resolved and increased by 100 mg/day at 1-week intervals until the goal serum urate concentration of <6 mg/dL (<357 μmol/L) is achieved. Febuxostat 40 to 80 mg/day can be used for patients intolerant to allopurinol or who have mild to moderate renal insufficiency. Colchicine (0.6 mg once daily) or an NSAID should be administered for at least the first 8 weeks of therapy to minimize the risk of acute attacks that may occur during initiation of uric acid–lowering therapy.
7. Uricosuric agents should be avoided for patients with renal impairment [a creatinine clearance below 50 mL/min (0.84 mL/s)], a history of renal calculi, or overproduction of uric acid.
8. Patients with hyperuricemia or gout should undergo comprehensive evaluation for signs and symptoms of cardiovascular disease, and aggressive management of cardiovascular risk factors (i.e., weight loss, reduction of alcohol intake, control of blood pressure, glucose, and lipids) should be undertaken as indicated.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The term *gout* describes a heterogeneous clinical spectrum of diseases including elevated serum urate concentration (hyperuricemia), recurrent attacks of acute arthritis associated with monosodium urate crystals in synovial fluid leukocytes, deposits of monosodium urate crystals (tophi) in tissues in and around joints, interstitial renal disease, and uric acid nephrolithiasis.[1]

The underlying metabolic disorder of gout is hyperuricemia, defined physiochemically as serum that is supersaturated with monosodium urate. At 37°C (98.6°F), serum urate concentrations above (or around) 7 mg/dL (416 μmol/L) begin to exceed the limit of solubility for monosodium urate.[1] For determination of the risk of gout, hyperuricemia is defined statistically as serum urate concentrations greater than 2 standard deviations above the population means for age- and sex-matched healthy populations, usually 7.0 mg/dL (416 μmol/L) for men and 6.0 mg/dL (357 μmol/L) for women.[1,2] Although hyperuricemia is fundamental to the development of gout, the mere presence of hyperuricemia itself is often an asymptomatic condition.

EPIDEMIOLOGY

Historically, gout has been referred to as the "disease of kings" since it was often associated with affluent societies and lifestyles of overindulgence, gluttony, and intemperance.[1] The incidence and prevalence of gout are increasing in Western industrialized countries, but contrary to history, the disease is no longer limited strictly to populations with a high standard of living.[3,4] Epidemiologic data indicate that the prevalence of gout is also increasing in less industrialized Eastern countries.[5–7] Numerous factors may explain this finding, including increased longevity, dietary habits, and increasing prevalence of obesity and the metabolic syndrome.

There is a direct correlation between serum uric acid concentration and both the incidence and prevalence of gout. Population studies have shown that serum urate concentration correlates with increasing age, serum creatinine, blood urea nitrogen, male gender, blood pressure, body weight, and alcohol intake. The incidence of gout is consistently higher for individuals who are obese or who consume large amounts of alcohol or higher amounts of meat or fish.[8–10]

Elevated serum urate levels are the single most important risk factor for the development of gout, and the relationship between the risk of an attack of acute gouty arthritis and serum urate levels is linearly correlated. The 5-year cumulative risk of gout for patients with serum urate concentrations <7 mg/dL (<416 μmol/L) is 0.6%, compared with a risk of 30.5% for those with urate levels >10 mg/dL (>595 μmol/L).[11] Sustained elevation of serum urate is virtually essential for the development of gout; however, hyperuricemia does not always lead to gout, and many patients with hyperuricemia remain asymptomatic.[2] Although unusual, acute gouty arthritis has been reported to occur in the presence of normal serum uric acid concentrations.[12]

Gout affects men about seven to nine times more often than women.[13] The incidence of gout increases with age, peaking at 30 to 50 years of age, with an annual incidence ranging from 1 in 1,000 for men ages 40 to 44 years and 1.8 in 1,000 for those ages 55 to 64 years.[10] The lowest rates of gout are observed in young women, approximately 0.8 cases per 10,000 patient-years.[14] Serum uric acid levels in women approach those of men once menopause has occurred; thus, in older age groups the gender gap narrows, and approximately half of newly diagnosed cases of gout are found in women.[2,4] Gout in men younger than 30 years of age or in premenopausal women may indicate an inherited enzyme defect or the presence of renal disease. Although no genetic marker has been isolated for gout, the familial nature of gout strongly suggests an interaction between genetic and environmental factors.

ETIOLOGY AND PATHOPHYSIOLOGY

In humans, the production of uric acid is the terminal step in the degradation of purines. Uric acid serves no known physiologic purpose and is regarded as a waste product. Normal uric acid levels are near the limits of urate solubility, because of the delicate balance that exists between the amount of urate produced and excreted.[15] Humans have higher uric acid levels than other mammals because they do not express the enzyme uricase, which converts uric acid to the more soluble allantoin.[16]

Gout occurs exclusively in humans in whom a miscible pool of uric acid exists. Under normal conditions, the amount of accumulated uric acid is about 1,200 mg in men and about 600 mg in women. The size of the urate pool is increased severalfold in individuals with gout. This excess accumulation may result from either overproduction or underexcretion of uric acid. Several conditions are associated with either decreased renal clearance or an overproduction of uric acid, leading to hyperuricemia. Table 102–1 lists some of these conditions.

OVERPRODUCTION OF URIC ACID

The purines from which uric acid is produced originate from three sources: dietary purine, conversion of tissue nucleic acid to purine nucleotides, and de novo synthesis of purine bases. The purines derived from these three sources enter a common metabolic pathway leading to the production of either nucleic acid or uric acid. Under normal circumstances, uric acid may accumulate excessively if production exceeds excretion. The average human produces about 600 to 800 mg of uric acid each day. Dietary purines play an unimportant role in the generation of hyperuricemia in the absence of some derangement in purine metabolism or elimination.

TABLE 102-1 Conditions Associated with Hyperuricemia

Primary gout	Obesity
Diabetic ketoacidosis	Sarcoidosis
Myeloproliferative disorders	Congestive heart failure
Lactic acidosis	Renal dysfunction
Lymphoproliferative disorders	Down syndrome
Starvation	Lead toxicity
Chronic hemolytic anemia	Hyperparathyroidism
Toxemia of pregnancy	Acute alcoholism
Pernicious anemia	Hypoparathyroidism
Glycogen storage disease type 1	Acromegaly
Psoriasis	Hypothyroidism
Hypoxanthine-guanine phosphoribosyltransferase deficiency	Phosphoribosylpyrophosphate synthetase overactivity
Polycythemia vera	Berylliosis
Renal transplantation	

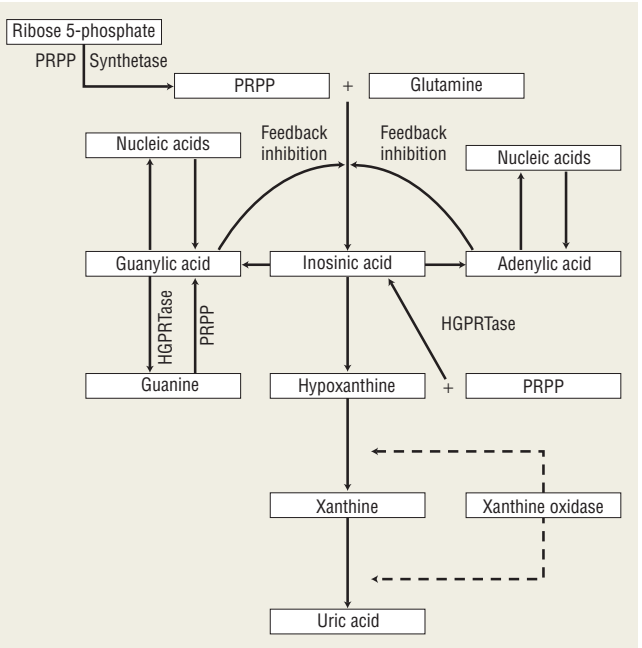

FIGURE 102-1. Purine metabolism (HGPRT, hypoxanthine-guanine phosphoribosyltransferase; PRPP, phosphoribosyl pyrophosphate).

However, diet modifications are important for patients with such problems who develop symptomatic hyperuricemia.

Several enzyme systems regulate purine metabolism. Abnormalities in these regulatory systems can result in overproduction of uric acid. Uric acid may also be overproduced as a consequence of increased breakdown of tissue nucleic acids and excessive rates of cell turnover, as observed with myeloproliferative and lymphoproliferative disorders, polycythemia vera, psoriasis, and some types of anemias. Cytotoxic medications used to treat these disorders can result in overproduction of uric acid secondary to lysis and breakdown of cellular matter.

Two enzyme abnormalities resulting in an overproduction of uric acid have been well described (Fig. 102–1). The first is an increase in the activity of phosphoribosyl pyrophosphate (PRPP) synthetase, which leads to an increased concentration of PRPP. PRPP is a key determinant of purine synthesis and uric acid production. The second is a deficiency of hypoxanthine-guanine phosphoribosyltransferase (HGPRT). HGPRT is responsible for the conversion of guanine to guanylic acid and hypoxanthine to inosinic acid. These two conversions require PRPP as the cosubstrate and are important reactions involved in the synthesis of nucleic acids. A deficiency in the HGPRT enzyme leads to increased metabolism of guanine and hypoxanthine to uric acid and to more PRPP to interact with glutamine in the first step of the purine pathway.[17] Complete absence of HGPRT results in the childhood Lesch-Nyhan syndrome, characterized by choreoathetosis, spasticity, mental retardation, and markedly excessive production of uric acid. A partial deficiency of the enzyme may be responsible for marked hyperuricemia in otherwise normal, healthy individuals.

UNDEREXCRETION OF URIC ACID

Normally, uric acid does not accumulate as long as production is balanced with elimination. About two thirds of the daily uric acid production is excreted in the urine and the remainder is eliminated through the gastrointestinal tract after enzymatic degradation by colonic bacteria. The vast majority of patients (80% to 90%) with gout have a relative decrease in the renal excretion of uric acid for an unknown reason (primary idiopathic hyperuricemia).[2]

TABLE 102-2 Drugs Capable of Inducing Hyperuricemia and Gout

Diuretics	Ethanol	Ethambutol
Nicotinic acid	Pyrazinamide	Cytotoxic drugs
Salicylates (<2 g/day)	Levodopa	Cyclosporine

A decline in the urinary excretion of uric acid to a level below the rate of production leads to hyperuricemia and an increased miscible pool of sodium urate. Almost all the urate in plasma is freely filtered across the glomerulus. The concentration of uric acid appearing in the urine is determined by multiple renal tubular transport processes in addition to the filtered load. Evidence favors a four-component model including glomerular filtration, tubular reabsorption, tubular secretion, and postsecretory reabsorption.

Approximately 90% of filtered uric acid is reabsorbed in the proximal tubule, probably by both active and passive transport mechanisms. There is a close linkage between proximal tubular sodium reabsorption and uric acid reabsorption; so conditions that enhance sodium reabsorption (e.g., dehydration) also lead to increased uric acid reabsorption. The exact site of tubular secretion of uric acid has not been determined; this too appears to involve an active transport process. Postsecretory reabsorption occurs somewhere distal to the secretory site. Table 102–2 lists the drugs that decrease renal clearance of uric acid through modification of filtered load or one of the tubular transport processes. By enhancing renal urate reabsorption, insulin resistance is also associated with gout.

The pathophysiologic approach to the evaluation of hyperuricemia requires determining whether the patient is overproducing or underexcreting uric acid. This can be accomplished by placing the patient on a purine-free diet for 3 to 5 days and then measuring the amount of uric acid excreted in the urine in 24 hours. As it is very difficult to maintain a purine-free diet for several days, this test is done infrequently in clinical practice. Nevertheless, when it is performed, individuals who excrete more than 600 mg on a purine-free diet may be considered overproducers. Hyperuricemic individuals who excrete less than 600 mg of uric acid per 24 hours on a purine-free diet may be classified as underexcreters of uric acid. On a regular diet, excretion of more than 1,000 mg per 24 hours reflects overproduction; less than this is probably normal.

CLINICAL PRESENTATION

1 Gout is diagnosed clinically by symptoms rather than laboratory tests of uric acid. In fact, asymptomatic hyperuricemia discovered incidentally generally requires no therapy because many individuals with hyperuricemia will never experience an attack of gout. These patients should still be encouraged to implement lifestyle measures to reduce serum urate concentrations.

PRESENTATION OF ACUTE GOUTY ARTHRITIS

General

- Gout classically presents as an acute inflammatory monoarthritis. The first metatarsophalangeal joint is often involved ("podagra"), but any joint of the lower extremity can be affected and occasionally gout will present as a monoarthritis of the wrist or finger. The spectrum of gout also includes nephrolithiasis, gouty nephropathy, and aggregated deposits of sodium urate (tophi) in cartilage, tendons, synovial membranes, and elsewhere.

Signs and Symptoms

- Fever, intense pain, erythema, warmth, swelling, and inflammation of involved joints

Laboratory Tests

- Elevated serum uric acid levels; leukocytosis

Other Diagnostic Tests

- Observation of monosodium urate crystals in synovial fluid or a tophus
- For patients with long-standing gout, radiographs may show asymmetric swelling within a joint on or subcortical cysts without erosions

ACUTE GOUTY ARTHRITIS

A classic acute attack of gouty arthritis is characterized by rapid and localized onset of excruciating pain, swelling, and inflammation. The attack is typically monarticular at first, most often affecting the first metatarsophalangeal joint (great toe) and then, in order of frequency, the insteps, ankles, heels, knees, wrists, fingers, and elbows. In one half of initial attacks, the first metatarsophalangeal joint is affected, a condition commonly referred to as *podagra* (see Fig. 102–2). Up to 90% of patients with gout will experience podagra at some point in the course of their disease.[15]

Atypical presentations of gout also occur. For elderly patients, gout can present as a chronic polyarticular arthritis that can be confused with rheumatoid arthritis or osteoarthritis. Additionally, the onset of gout may be less dramatic than the typical acute attack and have fewer clinical findings. Multiple small joints in the hands may be involved, especially in elderly women.[2] Table 102–3 summarizes the different clinical manifestations of gout.

The predilection of acute gout for peripheral joints of the lower extremity is probably related to the low temperature of these joints combined with high intraarticular urate concentration. Synovial effusions are likely to occur transiently in weight-bearing joints during the course of a day with routine activity. At night, water is reabsorbed from the joint space, leaving behind a supersaturated solution of monosodium urate, which can precipitate attacks of acute arthritis. Attacks generally begin at night with the patient awakened from sleep by excruciating pain.

The development of crystal-induced inflammation involves a number of chemical mediators causing vasodilation, increased vascular permeability, complement activation, and chemotactic activity for polymorphonuclear leukocytes.[18] Phagocytosis of urate crystals by the leukocytes results in rapid lysis of cells and a discharge of lysosomal and proteolytic enzymes into the cytoplasm.

FIGURE 102-2. Acute gout attack of the first metatarsophalangeal joint. *(From Imboden J, Hellmann DB, Stone JH. Current Rheumatology Diagnosis and Treatment, 2d ed. New York: McGraw-Hill, 2004:316.)*

TABLE 102-3 Clinical Manifestations of Gout

Classic acute gout ("podagra")	Monoarticular arthritis Frequently attacks the first metatarsophalangeal joint, although other joints of the lower extremities are also frequently involved. Affected joint is swollen, erythematous, and tender.
Interval gout	Asymptomatic period between attacks.
Tophaceous gout	Deposits of monosodium urate crystals in soft tissues. Complications include soft tissue damage, deformity, joint destruction, and nerve compression syndromes such as carpal tunnel syndrome.
Atypical gout	Polyarthritis affecting any joint, upper or lower extremity. May be confused with rheumatoid arthritis or osteoarthritis.
Renal effects	Nephrolithiasis Acute and chronic gouty nephropathy

The ensuing inflammatory reaction is associated with intense joint pain, erythema, warmth, and swelling. Fever is common, as is leukocytosis. Untreated attacks may last from 3 to 14 days before spontaneous recovery.

Although acute attacks of gouty arthritis may occur without apparent provocation, a number of conditions may precipitate an attack. These include stress, trauma, alcohol ingestion, infection, surgery, rapid lowering of serum uric acid by ingestion of uric acid-lowering agents, and ingestion of certain drugs known to elevate serum uric acid concentrations (see Table 102–2). Other crystal-induced arthropathies that may resemble gout on clinical presentation are caused by calcium pyrophosphate dihydrate crystals (pseudogout) and calcium hydroxyapatite crystals, which are associated with calcific periarthritis, tendinitis, and arthritis.[19,20]

Acute flares of gouty arthritis may occur infrequently, but over time the interval between attacks may shorten if appropriate measures to correct hyperuricemia are not undertaken. Later in the disease, tophaceous deposits of monosodium urate crystals in the skin or subcutaneous tissues may be found. These tophi can be anywhere but are often found on the hands, wrists, elbows, or knees. It is estimated to take 10 or more years for tophi to develop.

Diagnostic Evaluation

Table 102–4 lists the differential diagnosis of an acute monoarthritis.[21] A definitive diagnosis of gout requires aspiration of synovial fluid from the affected joint and identification of intracellular crystals of monosodium urate monohydrate in synovial fluid leukocytes.[2] Identification of monosodium urate crystals is highly dependent on the experience of the observer. Crystals are needle shaped, and when examined under polarizing light microscopy, they are strongly negatively birefringent (see Fig. 102–3). Crystals can be observed in synovial fluid during asymptomatic periods.[22] If an affected joint is tapped, the resulting synovial fluid may have white cells and appear purulent. Such findings should always raise the question of infection. If any clinical features of infection are present, such as high fever, elevated white blood cell count, multiple joints affected, or an identified source of infection, proper diagnosis and treatment are critical. Patients with gout can have septic arthritis. Diabetes, alcohol abuse, and advanced age increase the likelihood of septic arthritis.

TABLE 102-4 Differential Diagnosis of Acute Monoarthritis

1. Pseudogout (pyrophosphate crystal related arthritis)
2. Palindromic rheumatism
3. Seronegative inflammatory arthritis
4. Trauma or hemarthrosis
5. Septic arthritis
6. Cellulitis
7. Type II dyslipidemia
8. Unrelated hyperuricemia (as in psoriasis, hypertension) when joint pain is not caused by gout.

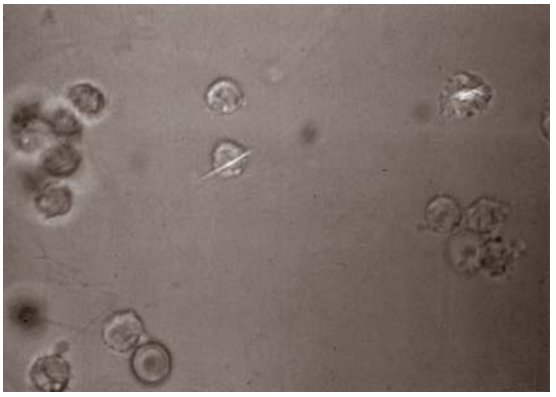

FIGURE 102-3. Urate crystal ingested by a polymorphonuclear leukocyte in synovial fluid. *(From Imboden J, Hellmann DB, Stone JH. Current Rheumatology Diagnosis and Treatment, 2d ed. New York: McGraw-Hill, 2004:317.)*

In lieu of obtaining a synovial fluid sample from an affected joint to inspect for urate crystals, the clinical triad of inflammatory monoarthritis, elevated serum uric acid level, and response to colchicine can be used to diagnose gout. However, this approach has limitations, including a failure to recognize atypical gout presentations and the fact that serum uric acid levels can be normal or even low during an acute gout attack.[11,23] In addition, use of colchicine as a diagnostic tool for gout is limited by lack of sensitivity and specificity for the disease. Other conditions such as psoriatic arthritis, sarcoidosis, and Mediterranean fever can respond to colchicine therapy. Table 102–5 shows the American College of Rheumatology classification criteria for an acute gouty arthritis attack.[24]

For patients with long-standing gout, radiographs may show punched-out marginal erosions and secondary osteoarthritic changes; however, in an acute first attack radiographs will be unremarkable.[21,25] The presence of chondrocalcinosis on radiographs may indicate pseudogout. Some studies have recently examined the use of magnetic resonance imaging and computed tomography to obtain images for patients with gout; however, this is not currently considered part of normal practice.

URIC ACID NEPHROLITHIASIS

Clinicians should be suspicious of hyperuricemic states for patients who present with kidney stones, as nephrolithiasis occurs in 10% to

TABLE 102-5 American College of Rheumatology Criteria for the Clinical Diagnosis of Gout[a]

1. More than one attack of acute arthritis
2. Maximum inflammation developed within 1 day
3. Monoarthritis attack
4. Redness observed over joints
5. First metatarsophalangeal joint painful or swollen
6. Unilateral first metatarsophalangeal joint attack
7. Unilateral tarsal joint attack
8. Tophus (proven or suspected)
9. Hyperuricemia
10. Asymmetric swelling within a joint on x-ray images
11. Subcortical cysts without erosions on x-ray images
12. Monosodium urate monohydrate microcrystals in joint fluid during attack
13. Joint fluid culture negative for organisms during attack

[a]The combination of crystals, tophi, and/or six or more criteria is highly suggestive of gout.
Source: Reference 24.

25% of patients with gout.[26] The frequency of urolithiasis depends on serum uric acid concentrations, acidity of the urine, and urinary uric acid concentration. Typically, patients with uric acid nephrolithiasis have a urinary pH of less than 6.0. Uric acid has a negative logarithm of the acid ionization constant of 5.5. Therefore, when the urine is acidic, uric acid exists primarily in the unionized, less soluble form. At a urine pH of 5.0, urine is saturated at a uric acid level of 15 mg/dL (0.89 mmol/L). When the urine pH is 7.0, the solubility of uric acid in urine is increased to 200 mg/dL (11.9 mmol/L).[1] For patients with uric acid nephrolithiasis, urinary pH typically is less than 6.0 and frequently less than 5.5. When acidic urine is saturated with uric acid, spontaneous precipitation of stones may occur.

Other factors that predispose individuals to uric acid nephrolithiasis include excessive urinary excretion of uric acid and highly concentrated urine. The risk of renal calculi approaches 50% in individuals whose renal excretion of uric acid exceeds 1,100 mg/day (6.5 mmol/day). In addition to pure uric acid stones, hyperuricosuric individuals are at increased risk for mixed uric acid–calcium oxalate stones and pure calcium oxalate stones. Uric acid stones are usually small, round, and radiolucent. Uric acid stones containing calcium are radiopaque.[26]

GOUTY NEPHROPATHY

There are two types of gouty nephropathy: acute uric acid nephropathy and chronic urate nephropathy.[27] In acute uric acid nephropathy, acute renal failure occurs as a result of blockage of urine flow secondary to massive precipitation of uric acid crystals in the collecting ducts and ureters. This syndrome is a well-recognized complication for patients with myeloproliferative or lymphoproliferative disorders and is a result of massive malignant cell turnover, particularly after initiation of chemotherapy.

Chronic urate nephropathy is caused by the long-term deposition of urate crystals in the renal parenchyma. Microtophi may form, with a surrounding giant-cell inflammatory reaction. A decrease in the kidneys' ability to concentrate urine and the presence of proteinuria may be the earliest pathophysiologic disturbances. Hypertension and nephrosclerosis are common associated findings. Although renal failure occurs in a higher percentage of gouty patients than expected, it is not clear if hyperuricemia per se has a harmful effect on the kidneys. The chronic renal impairment seen in individuals with gout may result largely from the coexistence of hypertension, diabetes mellitus, and atherosclerosis.

TOPHACEOUS GOUT

Tophi (urate deposits) are uncommon in the general population of gouty subjects and are a late complication of hyperuricemia. The most common sites of tophaceous deposits for patients with recurrent acute gouty arthritis are the base of the great toe, helix of the ear, olecranon bursae, Achilles tendon, knees, wrists, and hands (Fig. 102–4).[2] Eventually, even the hips, shoulders, and spine may be affected. In addition to causing obvious deformities, tophi may damage surrounding soft tissue, cause joint destruction and pain, and even lead to nerve compression syndromes including carpal tunnel syndrome.

TREATMENT

Gout and Hyperuricemia

The goals in the treatment of gout are to terminate the acute attack, prevent recurrent attacks of gouty arthritis, prevent complications associated with chronic deposition of urate crystals in tissues, and prevent or reverse features commonly associated with the illness including obesity, elevated triglycerides, and hypertension.[1] This can be accomplished through a combination of nonpharmacologic and pharmacologic methods. Table 102–6 summarizes the available pharmacotherapy for gout.

FIGURE 102-4. Tophaceous gout with subcutaneous nodule almost breaking through the skin. *(From South-Paul JE, Matheny SC, Lewis EL. Current Diagnosis and Treatment in Family Medicine. New York: McGraw-Hill, 2004:275.)*

■ ACUTE GOUTY ARTHRITIS

❷ For most patients without contraindications, acute attacks of gouty arthritis may be treated successfully with short courses of high-dose nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, or colchicine (Fig. 102–5).[28,29]

Nonsteroidal Antiinflammatory Drugs

NSAIDs are the mainstay of therapy for acute attacks of gouty arthritis because of their excellent efficacy and minimal toxicity with short-term use. Indomethacin has been historically favored as the NSAID of choice for acute gout flares, but there is little evidence to support one NSAID as being more efficacious than another. Three agents (indomethacin, naproxen, and sulindac) have actual U.S. Food and Drug Administration (FDA)-approved labeling for the treatment of gout, although several have been studied (see Table 102–6).[2] The most important determinant of therapeutic success with NSAIDs appears not to be which one is chosen but rather how soon it is initiated. Therapy should be initiated with maximum dosages at the onset of symptoms and continued for 24 hours after complete resolution of an acute attack, then tapered quickly over 2 to 3 days. Resolution of an acute attack for most patients generally occurs within 5 to 8 days after initiating therapy.

All NSAIDs have the potential to cause similar adverse effects. The most common areas affected include the gastrointestinal system (gastritis, bleeding, perforation), kidneys (renal papillary necrosis, reduced creatinine clearance), cardiovascular system (sodium and fluid retention, increased blood pressure), and central nervous system (impaired cognitive function, headache, dizziness). Caution should be exercised when using NSAIDs for individuals with a history of peptic ulcer disease, congestive heart failure, uncontrolled hypertension, renal insufficiency, coronary artery disease or who are concurrently receiving anticoagulants or antiplatelets. Patients with active peptic ulcer disease, uncompensated congestive heart failure, severe renal impairment, or a history of hypersensitivity to aspirin or other NSAIDs should not be prescribed an NSAID.

TABLE 102-6 Pharmacotherapy of Acute and Chronic Gout

Therapeutic Agent	Typical Regimen	Considerations
Acute gout		
Nonsteroidal antiinflammatory drugs		
Etodolac	300 mg twice daily	Avoid for patients with peptic ulcer disease, active bleeding. May cause renal dysfunction, gastritis (worse with concurrent aspirin), fluid retention, and hypertension. Use caution in congestive heart failure. Consider coadministration with a proton-pump inhibitor for patients at risk for gastrointestinal bleeding.
Fenoprofen	300–600 mg three to four times daily	
Ibuprofen	800 mg four times daily	
Indomethacin[a]	25–50 mg four times daily initially for 3 days, then taper to twice daily for 4–7 days	
Ketoprofen	75 mg four times daily	
Naproxen[a]	500 mg twice daily initially for 3 days, then 250–500 mg once daily for 4–7 days	
Piroxicam	20 mg once daily or divided twice daily	
Sulindac[a]	200 mg twice daily for 7–10 days	
Oral colchicine	1.2 mg initially, followed by 0.6 mg 1 hour later	In the presence of renal impairment, dosing should be repeated no more than once every 2 weeks. Dose-dependent gastrointestinal side effects (diarrhea, nausea, vomiting). Avoid coadministration with p-glycoprotein or strong CYP3A4 inhibitors (e.g., clarithromycin).
Corticosteroids		
Oral	30–60 mg prednisone equivalent once daily for 3–5 days, then taper in 5 mg decrements spread over 10–14 days until discontinuation	Use with caution in diabetics. Avoid long-term use. May cause fluid retention and impaired wound healing. Intraarticular administration is preferred for monoarticular involvement; avoid use if joint sepsis is not excluded.
Intramuscular	Triamcinolone acetonide 60 mg IM once, or methylprednisolone 100–150 mg/day for 1–2 days	
Intraarticular	Triamcinolone acetonide 10–40 mg (large joints), 5–20 mg (small joints)	
Corticotropin	25 USP units subcutaneously for acute small-joint monoarticular gout; 40 USP units IM or IV for larger joints or polyarticular involvement	Repeat injections (every 6–8 hours for 2–3 days) may be needed. Requires intact pituitary-adrenal axis. Less effective for patients receiving long-term oral corticosteroid therapy.
Intercritical gout		
NSAIDs	Lowest effective dosage	NSAID gastropathy (See above.)
Oral colchicine	0.6 once daily or every other day	Reversible axonal neuromyopathy and rhabdomyolysis.
Xanthine oxidase inhibitors		
Allopurinol	50–300 mg daily [can be titrated up to 800 mg/day to achieve serum urate concentration <6.0 mg/dL (<357 μmol/L)]	Can be used in both urate overproduction and urate underexcretion. Side effects include rash, gastrointestinal symptoms, and potential for fatal hypersensitivity syndrome. Dose reduction necessary for patients with renal insufficiency.
Febuxostat	40–80 mg/daily	Can be used for allopurinol-intolerant patients. No dosage adjustment necessary for patients with mild-moderate renal dysfunction [creatinine clearance 30–59 mL/min (0.50–0.99 mL/s)]. Side effects include liver enzyme elevations, nausea, arthralgias, and rash.
Uricosurics		
Probenecid	250 mg twice daily, titrated up to 500–2000 mg/day [target serum urate concentration <6 mg/dL (<357 μmol/L)]	Useful in urate underexcretion. Avoid for patients with history of urolithiasis.
Sulfinpyrazone	50 mg twice daily, titrated to 100–400 mg/day [target serum urate concentration <6 mg/dL (<357 μmol/L)]	

[a]FDA-approved for treatment of acute gouty arthritis.

Although the risk for gastric ulceration and bleeding is relatively small with short-term therapy normally employed when treating acute gout flares, consideration should be given to administering a proton pump inhibitor to protect from NSAID-induced gastric problems for elderly patients and for others who are at risk for these complications (e.g., presence of multiple comorbidities, alcoholism, previous history of ulcer, or concurrent anticoagulant use).[30,31] The efficacy and safety of selective cyclooxygenase-2 inhibitors have not been assessed for patients with gouty arthritis, but they are more costly than older NSAIDs and unlikely to result in fewer gastrointestinal complications because of the short courses of therapy routinely used to treat acute attacks.

Corticosteroids

Corticosteroids have typically been reserved for treatment of acute gout flares when contraindications to NSAIDs exist, largely due to lack of evidence from controlled clinical trials. However, evidence that is more recent indicates that corticosteroids are equivalent to NSAIDs in the treatment of acute gout flares.[29] They can be used either systemically or by intraarticular injection. Oral corticosteroids are usually administered in doses of 30 to 60 mg of prednisone equivalent for 3 to 5 days.[2] Patients with multiple joint involvement may be good candidates to consider for this regimen.

A hypothetical risk for a rebound attack upon steroid withdrawal exists; therefore, the dose of corticosteroid should be tapered gradually in 5 mg decrements spread over 10 to 14 days and then discontinued. Intraarticular administration of triamcinolone acetonide in a dose of 20 to 40 mg may be useful in treating acute gout limited to one or two joints. Injection should be done under aseptic technique in a joint determined not to be infected. A single intramuscular injection of a long-acting corticosteroid, such as methylprednisolone, can be used as an alternative to the oral route if patients are unable to take oral therapy.[2] If not contraindicated,

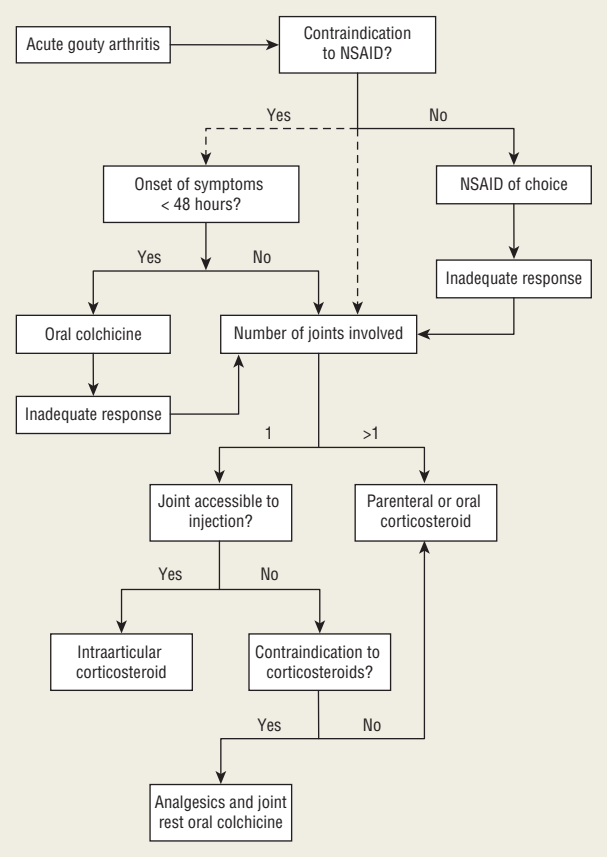

FIGURE 102-5. Treatment algorithm for acute gouty arthritis (NSAID, nonsteroidal antiinflammatory drug).

low-dose colchicine can be used as adjunctive therapy to injectable corticosteroids to prevent rebound flare-ups.

The adverse effects of corticosteroids are generally dose and duration dependent. Short-term use for treatment of acute attacks is generally well tolerated. Corticosteroids should be used with caution for patients with diabetes as they can increase blood sugar. In addition, patients with a history of gastrointestinal problems, bleeding disorders, cardiovascular disease, and psychiatric disorders should be monitored closely. Long-term corticosteroid use should be avoided because of the risk for osteoporosis, hypothalamic–pituitary axis suppression, cataracts, and muscle deconditioning that can occur with their use.

CLINICAL CONTROVERSY

NSAIDs have historically been used as the first-line therapy for treatment of acute attacks of gout. Some clinicians prefer to start therapy instead with a corticosteroid, believing them to be tolerated better and equally effective. Presently, there is no compelling evidence for superiority of either class of agents. The choice of therapy should be individualized based on the characteristics of the patient and the profile of the drug(s). Regardless of the selection, therapy should be initiated quickly, and side effects carefully monitored.

Corticotropin, or adrenocorticotropic hormone (ACTH), which stimulates the adrenal cortex to produce cortisol and corticosterone, can be administered in acute gout. Doses of 40 to 80 United States Pharmacopeia (USP) units are given intramuscularly every 6 to 8 hours for 2 to 3 days, and then discontinued. Studies with ACTH are limited, but it appears to provide similar efficacy to systemic antiinflammatory doses of corticosteroids.[32] When administered alone or in combination with colchicine, ACTH may provide earlier efficacy compared with indomethacin but with fewer adverse effects.[33] Unfortunately, ACTH is often difficult to obtain in the United States as a result of manufacturing problems. Because the studies have several limitations, the regimen should be considered only as an alternative, one that is especially for patients with comorbidities where other regimens are contraindicated.[34] Examples of patients where ACTH has been used safely when other first-line gout therapies were contraindicated include those with congestive heart failure, chronic renal failure, and history of gastrointestinal bleeding.[35]

Colchicine

3 Colchicine is an antimitotic drug that is highly effective at relieving acute attacks of gout but has the lowest benefit-to-toxicity ratio of the available pharmacotherapy for gout.[36] When begun within the first 24 hours of an acute attack, colchicine produces a response in two thirds of patients within hours of administration.[37] If the initiation of colchicine is delayed longer than 48 hours after the onset of acute symptoms, the probability of success with the drug diminishes substantially. Although it is a highly effective therapy, oral colchicine can cause dose-dependent gastrointestinal adverse effects, including nausea, vomiting, and diarrhea, in 50% to 80% of patients.[2] Other important nongastrointestinal adverse effects include neutropenia and axonal neuromyopathy, which may be worsened for patients taking other myopathic drugs such as β-hydroxy-β-methylglutaryl-coenzyme A reductase inhibitors (statins) or for those with renal insufficiency.

Colchicine has been used for many years as an unapproved drug with no FDA-approved prescribing information, dosage recommendations, or drug interaction warnings. Recently, the FDA approved a 0.6 mg tablet of colchicine (Colcrys) for oral use. Data submitted in support of the safety and efficacy of colchicine in acute gout flares demonstrated that a substantially lower dose of colchicine (1.2 mg initially, followed by 0.6 mg 1 hour later) was as effective as higher doses traditionally used (continued hourly dosing until symptoms subside or gastrointestinal symptoms become intolerable).[38] These findings suggest that prior use of high-dose colchicine regimens, as traditionally recommended, may unnecessarily expose patients to increased toxicity with no additional efficacy. Additionally, comprehensive review of postmarketing safety data revealed an increased risk of adverse events for patients receiving colchicine administered concurrently with P-glycoprotein or cytochrome P450 3A4 inhibitors (e.g., clarithromycin).[39–42] This interaction is thought to result from decreased biliary excretion of colchicine leading to increased plasma levels of colchicine.

Colchicine should be used carefully for patients with renal insufficiency, with dosing repeated no more than once every 2 weeks. Patients undergoing dialysis should receive a reduced dose of 0.6 mg, administered as a one-time dose only. As a consequence of the high incidence of adverse effects and the low benefit-to-toxicity ratio, colchicine is used less often than NSAIDs in the United States, and it should be reserved as a second-line therapy when NSAIDs or corticosteroids are contraindicated or ineffective.

Intravenous colchicine has resulted in fatalities and is no longer available.[43]

Nonpharmacologic Therapies

Gout is influenced by several dietary factors, including obesity, alcohol intake, hyperlipidemia, and the insulin resistance syndrome.[44] Because of the elevated risk for development of gout that

exists with hyperuricemia, even the asymptomatic patient should receive interventions directed toward modifying or correcting some of these underlying contributors.

Patients suffering from acute gouty arthritis should be advised to reduce their dietary intake of saturated fats and meats high in purines (e.g., organ meats). Some consideration may be given to a rigid purine-free diet, although they may only be moderately effective in lowering serum uric acid levels and they can rarely be sustained for long periods of time.[44] Because of the increased risk of developing nephrolithiasis, clinicians should counsel patients with gout to increase fluid intake and decrease salt consumption.[45] In addition, joint rest for 1 to 2 days should be encouraged, and local application of ice may be beneficial.[44,46] Joint exercise and application of heat to the affected area should be avoided, as they can worsen the condition.

Weight loss through caloric restriction and exercise should be promoted in all patients with gout or asymptomatic hyperuricemia, and this may enhance renal excretion of urate.[47] Restriction of alcohol intake is of great importance, as alcohol consumption is closely correlated with gout symptoms.[8] Acute ingestions of alcohol cause lactic acidemia, which reduces renal urate excretion, whereas long-term alcohol intake promotes production of purines as a by-product of the conversion of acetate to acetyl coenzyme A in the metabolism of alcohol.[44]

The presence of gout should not be a contraindication to the use of thiazide diuretics in hypertensive patients, although clinicians should be aware that diuretics are independent risk factors for gout and can increase serum uric acid levels.[9] It may be important to avoid using diuretics if other agents can be used to control blood pressure, particularly if the patient has had frequent gout attacks or continues to have an elevated serum uric acid level despite appropriate therapy for gout.

NEPHROLITHIASIS

4 The medical management of uric acid nephrolithiasis includes hydration sufficient to maintain a urine volume of 2 to 3 L/day, alkalinization of urine, avoidance of purine-rich foods, moderation of protein intake, and reduction of urinary uric acid excretion.

Maintenance of a 24-hour urine volume of 2 to 3 L with an adequate intake of fluids is desirable for all gout patients, but especially for those with excessive [>1 g/day (>6 mmol/day)] uric acid excretion. Alkalinizing agents should be used with the objective of making the urine less acidic. Urine pH should be maintained at 6 to 6.5. In this pH range, up to 85% of uric acid will be in the form of the soluble urate ion.

Reduction of urine acidity is usually accomplished by the administration of potassium bicarbonate or potassium citrate 60 to 80 mEq/day.[48,49] Administration of alkali via sodium salts is a less desirable option for two reasons. First, the sodium-induced volume expansion will increase sodium excretion and can secondarily cause hypercalcemia because calcium passively follows the reabsorption of sodium in the proximal tubule and loop of Henle. In the presence of uric acid, the resultant hypercalcemia can lead to calcium oxalate stone formation. Second, older patients with uric acid kidney stones may also have hypertension, congestive heart failure, or renal insufficiency. Because of these conditions, they should not be overloaded with alkalinizing sodium salts or unlimited fluid intake, as these agents can worsen these conditions. Acetazolamide, a carbonic anhydrase inhibitor, produces rapid and effective urinary alkalinization and sometimes is used in conjunction with alkali therapy. When a 250 mg dose of acetazolamide is given at bedtime, the excretion of acidic urine in the early morning hours is avoided. The usual tachyphylaxis (rapid tolerance) to this drug is obviated by a daily repletion dose of bicarbonate.

Since the advent of xanthine oxidase inhibitors, a low-purine, low-protein diet for the patient with uric acid nephrolithiasis is no longer as critical as it once was; however, it is still advisable to instruct the patient to avoid foods rich in purine and to limit protein to no more than 90 g/day. Such a diet is still palatable and reduces appreciably the amount of uric acid in the urine.

The mainstay of drug therapy for recurrent uric acid nephrolithiasis is xanthine oxidase inhibitors. They are effective in reducing both serum and urinary uric acid levels, thus preventing the formation of calculi. Xanthine oxidase inhibitors are recommended as prophylactic treatment for patients who will receive cytotoxic agents for the treatment of lymphoma or leukemia. The marked increase in uric acid production associated with cytolysis of a neoplasm predisposes a patient to the development of uric acid nephrolithiasis.

PROPHYLACTIC THERAPY OF INTERCRITICAL GOUT

5 After the first attack of acute gouty arthritis or after the passage of the first renal stone, a decision to institute prophylactic therapy must be considered. This decision should carefully balance risk and benefit. Prophylactic therapy has been found to be cost-effective if patients have two or more attacks per year, even if the serum uric acid concentration is normal or only minimally elevated.[50,51]

If the first episode was mild and responded promptly to treatment, the patient's serum urate concentration was elevated only minimally, and the 24-hour urinary uric acid excretion was not excessive [<1,000 mg/24 hours (<5.95 mmol/day) on a regular diet], then prophylactic treatment can be withheld. Some patients never have a second attack or a second stone. Others may not experience a second gouty episode for 5 to 10 years. Consequently, a wait-and-see approach seems justified for patients who meet these conditions.[52]

On the other hand, if the patient had a severe attack of gouty arthritis, a complicated course of uric acid nephrolithiasis, a substantially elevated serum uric acid level [>10 mg/dL (>595 μmol/L)], or a 24-hour urinary excretion of uric acid of more than 1,000 mg (5.95 mmol), then prophylactic treatment should be instituted immediately after resolution of the acute episode. Patients with tophi should also be administered prophylactic therapy. When implemented, urate-lowering therapy should not commence during an acute attack but 6 to 8 weeks after resolution.

Prophylactic therapy with low-dose oral colchicine, 0.6 mg once daily, may be effective in preventing recurrent arthritis for patients with no evidence of visible tophi and a normal or slightly elevated serum urate concentration. Patients do not become resistant to or tolerant of daily colchicine, and if they sense the beginning of an acute attack, they should increase the dose to 1.2 mg, followed by one repeat dose of 0.6 mg in 1 hour. If the serum urate concentration is within the normal range and the patient has been symptom free for 1 year, maintenance colchicine may be discontinued. The patient should be advised, however, that discontinuation of the treatment program may be followed by an exacerbation of acute gouty arthritis.

Patients with a history of recurrent acute gouty arthritis and a significantly elevated serum uric acid concentration probably are best managed with uric acid–lowering therapy. The goal of initiating urate-lowering therapies is to achieve and maintain a serum uric acid concentration of less than 6 mg/dL (357 μmol/L), and preferably below 5 mg/ dL (297 μmol/L).[52] Reduction of the serum urate concentration can be accomplished pharmacologically by decreasing the synthesis of uric acid (xanthine oxidase inhibitors) or by increasing the renal excretion of uric acid (uricosurics). Colchicine at a dose of 0.6 mg once daily should be administered for at least the

first 8 weeks of antihyperuricemic therapy to minimize the risk of acute attacks that may occur during initiation of uric acid–lowering therapy.

Xanthine Oxidase Inhibitors

6 Xanthine oxidase inhibitors reduce uric acid by impairing the ability of xanthine oxidase to convert hypoxanthine to xanthine and xanthine to uric acid. Because they are efficacious for prophylaxis in both underexcreters and overproducers of uric acid, xanthine oxidase inhibitors are the most widely prescribed agents for the long-term prevention of recurrent attacks of gout. For nearly 40 years, allopurinol was the only agent available in the United States; however, a second xanthine oxidase inhibitor (febuxostat; Uloric) was recently made available.

Allopurinol lowers uric acid levels in a dose-dependent manner. Because of the long half-life of its metabolite (oxypurinol), it can be given once daily. It is typically initiated at a dose of 100 mg/day and then titrated by 100 mg/day at 1-week intervals to achieve a serum uric acid level of 6 mg/dL (357 μmol/L) or less, which will promote shrinkage of tophi.[53] Serum uric acid levels can be checked approximately 1 week after initiating or modifying the dose of allopurinol. Typical doses of 100 to 300 mg/day are used, although tophaceous gout may require doses of 400 to 600 mg/day and the maximum recommended dose of allopurinol is 800 mg/day. Allopurinol should be considered for long-term use when prescribed, as intermittent administration has been found to be less effective in controlling gouty attacks.[54]

Allopurinol is an effective urate-lowering agent, but up to 5% of patients are unable to tolerate it because of adverse effects, and long-term adherence with allopurinol is low.[55] Mild adverse effects such as skin rash, leukopenia, gastrointestinal problems, headache, and urticaria can occur with allopurinol administration. More severe adverse reactions including severe rash (toxic epidermal necrolysis, erythema multiforme, or exfoliative dermatitis), hepatitis, interstitial nephritis, and eosinophilia reportedly occur in approximately 2% of patients and are associated with a 20% mortality.[56] Although direct evidence is lacking, the presence of renal insufficiency is believed to predispose patients to this "allopurinol hypersensitivity syndrome."[56] It is traditionally recommended that the dose of allopurinol be reduced for patients with renal insufficiency [200 mg/day for creatinine clearance of 60 mL/min (1.00 mL/s), and 100 mg/day for creatinine clearance of 30 mL/min (0.50 mL/s)].

Similar to allopurinol, febuxostat lowers serum urate concentrations in a dose-dependent manner.[57,58] In clinical trials, 40 mg/day of febuxostat was noninferior to conventionally dosed allopurinol (300 mg/day) in achieving the primary endpoint of serum urate concentration <6.0 mg/dL (<357 μmol/L), while 80 mg/day of febuxostat was more effective. The incidence of gout flares occurring during the initial months of administration was similar for both drugs. Febuxostat is well tolerated, with adverse events mostly limited to nausea, arthralgias, and minor liver transaminase elevations.

One criticism of the studies comparing allopurinol and febuxostat is that a fixed dose of allopurinol was used, rather than titrating the dose to achieve the targeted serum urate level. However, the 300 mg/day dosing of allopurinol reflects what is typically used in the majority of clinical practice.[59]

An advantage of febuxostat is that it does not require dose adjustment for patients with mild to moderate hepatic or renal impairment [creatinine clearances of 30 to 89 mL/min (0.50 to 1.49 mL/s)]. Due to the rapid mobilization of urate deposits occurring with initiation of febuxostat, concomitant therapy with colchicine or a NSAID to prevent acute gout flares should be overlapped for at least the first 8 weeks after initiation of therapy.

CLINICAL CONTROVERSY

Which xanthine oxidase inhibitor is preferred for use? Although allopurinol is approved for treatment of hyperuricemia in doses up to 800 mg/day, the majority of prescriptions for allopurinol are for doses ≤300 mg/day, a dose that is inadequate to achieve serum urate concentration <6.0 mg/dL (<357 μmol/L) for many patients. The underdosing of allopurinol is likely due to the belief that dose should be calibrated to renal function in order to avoid the rare allopurinol hypersensitivity syndrome. Unfortunately, little evidence examines the risk-to-benefit ratio of uptitrating doses of allopurinol to optimize urate lowering, and severe allopurinol hypersensitivity reactions are not necessarily dose dependent. Febuxostat is more potent on a milligram-per-milligram basis in lowering serum urate than allopurinol, but there is no evidence to suggest superiority of effect in reducing recurrent gout attacks when equipotent doses are used.

Uricosuric Drugs

Uricosuric drugs increase the renal clearance of uric acid by inhibiting postsecretory renal proximal tubular reabsorption of uric acid. The drugs used most widely to increase uric acid excretion are probenecid and sulfinpyrazone. Several other uricosuric drugs are available in Europe, but they have not been approved for use in the United States.

Therapy with uricosuric drugs should be started at a low dose to avoid marked uricosuria and possible stone formation. They should be used only for patients with documented underexcretion of urate (less than 800 mg in 24 hours on a regular diet or 600 mg on a purine-restricted diet). The maintenance of adequate urine flow and alkalinization of the urine during the first several days of uricosuric therapy further diminish the possibility of uric acid stone formation. Probenecid is given initially at a dose of 250 mg twice a day for 1 to 2 weeks and then 500 mg twice a day for 2 weeks. Thereafter the daily dose is increased by 500 mg increments every 1 to 2 weeks until satisfactory control is achieved or a maximum dose of 2 g is reached. The initial dose of sulfinpyrazone is 50 mg twice a day for 3 to 4 days and then 100 mg twice a day, increasing the daily dose by 100 mg increments each week up to 800 mg/day.

The major adverse effects associated with uricosuric therapy are gastrointestinal irritation, rash and hypersensitivity, precipitation of acute gouty arthritis, and stone formation. Of the two agents, probenecid is the most frequently used uricosuric, as sulfinpyrazone is associated with more severe adverse effects. A disadvantage of uricosurics is that salicylates may interfere with this mechanism and result in treatment failure; however, low doses (325 mg/day or less) of enteric-coated aspirin may be used cautiously. In addition, probenecid can inhibit the tubular secretion of other organic acids; thus, increased plasma concentrations of penicillins, cephalosporins, sulfonamides, and indomethacin can occur. Because it is chemically related to phenylbutazone, sulfinpyrazone can act as an antiplatelet agent and should be used with great caution for anticoagulated patients or for those with peptic ulcer disease.

7 Uricosuric drugs are contraindicated for patients who are allergic to them and for patients with impaired renal function [a creatinine clearance <50 mL/min (<0.84 mL/s)] and a history of renal calculi and for patients who are overproducers of uric acid; for such patients, a xanthine oxidase inhibitor should be used.

Miscellaneous Agents

Several other medications have been effective in gout. Benzbromarone is a uricosuric that is efficacious for patients with renal

insufficiency, but it is not available in the United States.[2] Oxypurinol, a metabolite of allopurinol, is not commercially available in the United States but can be obtained through the manufacturer on a compassionate basis.[44] Several newer medications, including uric acid oxidase (uricase), are currently under investigation and may offer additional options in the future.[44] A recombinant form of uricase (rasburicase) is currently available and indicated for use in the management of hyperuricemia in children with leukemia, lymphoma, or solid-tumor malignancies who are likely to experience tumor lysis syndrome. The efficacy of rasburicase has not been assessed outside of the oncology setting in adults with acute gouty arthritis.

Lipid-lowering agents, in particular fenofibrate, can also be prescribed for patients with gout. Although dyslipidemia is common in gout patients, the fibrates are believed to exert their effects as an ancillary benefit by increasing the clearance of hypoxanthine and xanthine, leading to a sustained reduction in serum urate concentrations. Reductions of 20% to 30% in urate levels are observed with fenofibrate use.[60,61] Importantly, fenofibrate does not appear to not cause an acute gout flare when initiated and is well tolerated overall.[62,63]

Losartan, an angiotensin II receptor antagonist, has also demonstrated benefit in reducing serum urate concentrations independently of angiotensin receptor antagonism.[64] Losartan inhibits renal tubular reabsorption of uric acid and increases urinary excretion, and this effect seems to be a unique property of losartan that is not shared with other angiotensin II receptor antagonists.[65] In addition, it alkalinizes the urine, which helps reduce the risk for stone formation.

ASYMPTOMATIC HYPERURICEMIA

Questions are often raised regarding the indications for drug therapy for asymptomatic hyperuricemia. The purported benefits include prevention of acute gouty arthritis, tophi formation, nephrolithiasis, and chronic urate nephropathy. The first three complications are easily controlled should they develop; therefore, antihyperuricemic therapy is not warranted to prevent these conditions. The prevention of urate nephropathy might be a stronger indication because it is irreversible even with proper treatment. Available data indicate, however, that gouty nephropathy is extremely rare in the absence of clinical gout, and evidence that elevation of uric acid by itself may cause renal disease is weak and inconclusive. As discussed previously, renal impairment is very rare in the absence of concurrent hypertension and atherosclerosis. In addition, it is unclear whether uric acid–lowering therapy protects renal function in such individuals. Thus, the routine treatment of asymptomatic hyperuricemia on the grounds of reducing renal complications is presently not recommended.

The relationship between elevated serum urate concentrations and cardiovascular disease is controversial. In observational studies, hyperuricemia has been shown to be a risk factor for ischemic heart disease.[66–69] However, hyperuricemia is also associated with other known risk factors for cardiovascular disease, such as diabetes mellitus, dyslipidemia, and hypertension, and the individual contribution of hyperuricemia on the risk for cardiovascular disease is difficult to separate from these associated factors. Recently, a 12-year follow-up of the Health Professionals Study revealed a 28% higher risk of death from all causes, 38% higher risk of cardiovascular disease death, 55% higher risk of death from coronary heart disease, and a 59% higher risk of nonfatal myocardial infarction for men with a self-reported history of gout compared with those who do not have these conditions.[70] These associations remained significant even after adjusting for age, body mass index, smoking, family history of myocardial infarction, and comorbidities such as diabetes and hypertension. To date, this study is the only one providing prospective data that implicate gout as an independent risk for coronary heart disease. No studies have examined whether drug treatment of asymptomatic hyperuricemia or gout is protective against coronary artery disease. At this time, it is premature to implement therapy for patients with asymptomatic hyperuricemia in the absence of a history of gout. Instead, efforts should be directed toward aggressive management of cardiovascular risk factors.

CLINICAL CONTROVERSY

While asymptomatic hyperuricemia is not generally treated, some clinicians have begun recommending treatment to reduce the risk of coronary artery disease. Hyperuricemia is associated with both hypertension and coronary artery disease, and patients with elevated uric acid levels and hypertension may have an increased risk of cardiovascular morbidity and mortality.

PHARMACOECONOMIC CONSIDERATIONS

Assuming patients with asymptomatic hyperuricemia are not treated with pharmacologic therapy, pharmacoeconomic considerations apply only to the management of the acute and chronic clinical manifestations of gout.

In a cost-effectiveness analysis for patients with nontophaceous recurrent gouty arthritis, urate-lowering therapy was found to reduce costs if patients experienced two or more recurrent attacks per year.[50] Generic allopurinol was associated with a lower incremental cost-effectiveness ratio than were either probenecid or sulfinpyrazone. No studies have examined the cost-effectiveness of febuxostat.

In the case of chronic tophaceous gout, the need to continue long-term therapy with a urate-lowering drug clearly exists. Allopurinol is less expensive than uricosuric therapy and may be more effective. Comparative trials are lacking. For severe cases, combination therapy may be indicated. Many clinicians will add colchicine to the regimen to reduce the likelihood of precipitating acute gouty arthritis, but this does not appear to be a cost-effective measure.

EVALUATION OF THERAPEUTIC OUTCOMES

Follow-up of the gout sufferer depends on the frequency of attacks and on the medications used to treat symptoms. For a patient who is experiencing a first attack of gout, long-term therapy is generally not indicated. As previously mentioned, most experts agree that treatment should be started only after two or three attacks of gout, because the treatment is long term and relatively expensive, the drugs used are potentially toxic, and adherence for patients without symptoms is generally poor.[51,55] Patients having a first attack should be educated about the likelihood of recurrence and what to do if another attack occurs. Approximately 60% of patients have a second attack within the first year, and 78% have a second attack within 2 years. Only 7% of patients do not have a recurrence within a 10-year period.[71]

Baseline blood work for patients receiving hypouricemic medications chronically should include renal function (serum creatinine, blood urea nitrogen), liver enzymes (aspartate aminotransferase, alanine aminotransferase), complete blood count, and electrolytes. There is generally no need to recheck these laboratory parameters for patients undergoing acute therapy with an NSAID or colchicine of limited duration. However, for

patients requiring long-term therapy or prophylaxis, they should be rechecked every 6 to 12 months or as clinically indicated. For patients without evident tophi, consideration can be given to discontinuing long-term therapy 6 to 12 months after normal serum urate levels are obtained.

For patients suspected of having an acute attack of gouty arthritis, it is reasonable to check a serum uric acid level, particularly if it is not the first attack and a decision is to be made regarding initiation of prophylactic therapy. However, clinicians should be mindful that acute gouty arthritis can occur in the presence of normal serum uric acid concentrations.[12] Repeat serum uric acid levels do not need to be routinely monitored in patients, with the exception of during the titration phase of allopurinol or febuxostat to achieve a goal serum urate concentration of <6 mg/dL (<357 μmol/L).[72]

8 Because of comorbidity with diabetes mellitus, lipid abnormalities, hypertension, and stroke, elevated uric acid levels or gout should prompt evaluations for signs of cardiovascular disease and the need for appropriate risk reduction measures.[28] Additionally, clinicians should look for a possible correctable cause of hyperuricemia, such as medications (e.g., thiazide diuretics, niacin, cyclosporine), obesity, malignancy, and alcohol abuse. Patients should be encouraged to exercise, lose weight, reduce alcohol intake, and control blood pressure and to have periodic follow-up to address these conditions.

CONCLUSIONS

Hyperuricemia may lead to acute arthritis, chronic gout, or kidney stones or to no sequelae at all. Asymptomatic hyperuricemia need not be treated, although lifestyle modifications (e.g., weight loss, reduction of alcohol intake, control of blood pressure) should be encouraged to help reduce serum urate and overall cardiovascular health.

Acute gouty arthritis responds well to short courses of NSAIDs to treat the underlying inflammatory condition. Colchicine is also highly effective, but has the lowest benefit-to-toxicity ratio of the available pharmacotherapy for acute gouty arthritis. Oral or intraarticular corticosteroids can be used, particularly if contraindications to NSAIDs or colchicine are present, there is lack of response to these agents, or polyarticular involvement is noted. The management of uric acid nephrolithiasis includes hydration and alkalinization of the urine. Prevention of recurrent gouty arthritis or recurrent nephrolithiasis and treatment of chronic gout require hypouricemic therapy with either a uricosuric drug or xanthine oxidase inhibitor. Xanthine oxidase inhibitors are effective in both underexcreters and overproducers of uric acid, making them the hypouricemic drugs of choice for most patients with gout.

ABBREVIATIONS

ACTH: adrenocorticotropic hormone

HGPRT: hypoxanthine guanine phosphoribosyl transferase

NSAID: nonsteroidal antiinflammatory drug

PRPP: phosphoribosyl pyrophosphate (synthetase)

SECTION 13
OPHTHALMIC AND OTOLARYNGOLOGICAL DISORDERS

CHAPTER 103

Glaucoma

RICHARD G. FISCELLA, TIMOTHY S. LESAR, AND DEEPAK P. EDWARD

KEY CONCEPTS

1. Primary open-angle glaucoma (POAG) or ocular hypertension is more prevalent than closed- or narrow-angle glaucoma.
2. In any form of glaucoma, reduction of intraocular pressure (IOP) is essential.
3. IOP is a very important risk factor for glaucoma, but the most important considerations are progression of glaucomatous changes in the back of the eye (optic disk and nerve fiber layer) and visual field changes when diagnosing and monitoring for POAG or ocular hypertension.
4. Optic nerve changes often occur before visual field changes are exhibited.
5. Recent studies demonstrate that reduction in IOP prevents progression or even onset of glaucoma.
6. Newer medications simplify treatment regimens for patients. Prostaglandin analogs are considered the most potent topical medications for reducing IOP and flattening diurnal variations in intraocular pressure.
7. Local adverse events are common with topical glaucoma medications, but patient education and reinforcing adherence are essential to prevent glaucoma progression.

The glaucomas are a group of ocular disorders that lead to an optic neuropathy characterized by changes in the optic nerve head (optic disk) that is associated with loss of visual sensitivity and field. Increased intraocular pressure (IOP), a traditional diagnostic criterion for glaucoma, is thought to play an important role in the pathogenesis of glaucoma, but it is no longer a diagnostic criterion for glaucoma.[1–10] Two major types of glaucoma have been identified: open angle and closed angle. Open-angle glaucoma accounts for the great majority of cases. Either type can be a primary inherited disorder, congenital, or secondary to disease, trauma, or drugs and can lead to serious complications.[11–16] Both primary and secondary glaucomas may be caused by a combination of open-angle and closed-angle mechanisms (Table 103–1).

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

BASIC CONCEPTS

AQUEOUS HUMOR DYNAMICS AND INTRAOCULAR PRESSURE

An understanding of IOP and aqueous humor dynamics will assist the reader in understanding the drug therapy of glaucoma.[1,2,17–19]

Aqueous humor is formed in the ciliary body and its epithelium (Figs. 103–1 and 103–2) through both filtration and secretion. Because ultrafiltration depends on pressure gradients, blood pressure and IOP changes influence aqueous humor formation. Osmotic gradients produced by active secretion of sodium and bicarbonate and possibly by other solutes such as ascorbate from the ciliary body epithelial cells into the aqueous humor result in movement of water from the pool of ciliary stromal ultrafiltrate into the posterior

chamber, forming aqueous humor. Carbonic anhydrase (primarily isoenzyme type II), α- and β-adrenergic receptors, and sodium- and potassium-activated adenosine triphosphatases are found on the ciliary epithelium and appear to be involved in this secretion of the solutes sodium and bicarbonate.

Receptor systems controlling aqueous inflow have not been elucidated fully. Pharmacologic studies suggest that β-adrenergic agents increase inflow, whereas α_2-adrenergic blocking, β-adrenergic blocking dopamine-blocking, carbonic anhydrase-inhibiting, and adenylate cyclase-stimulating agents decrease aqueous inflow. Aqueous humor produced by the ciliary body is secreted into the posterior chamber at a rate of approximately 2 to 3 µL/min. The pressure in the posterior chamber produced by the constant inflow pushes the aqueous humor between the iris and lens and through the pupil into the anterior chamber of the eye (see Fig. 103–2).[1,2,17–22]

Aqueous humor in the anterior chamber leaves the eye by two routes: (1) filtration through the trabecular meshwork (conventional outflow) to the Schlemm canal (80% to 85%) and (2) through the ciliary body and the suprachoroidal space (uveoscleral outflow or unconventional outflow). Cholinergic agents such as pilocarpine increase outflow by physically opening the meshwork pores secondary to ciliary muscle contraction. The uveoscleral outflow of aqueous humor is also increased by prostaglandin analogs and β- and α_2-adrenergic agonists. Constant inflow of aqueous humor from the ciliary body and resistance to outflow result in an IOP great enough to produce an outflow rate equal to the inflow rate (see Fig. 103–2).

The median IOP measured in large populations is 15.5 ± 2.5 mm Hg (2.1 ± 0.3 kPa); however, the distribution of pressures around the mean is skewed to the right (toward higher readings). IOP is not constant and changes with pulse, blood pressure, forced expiration or coughing, neck compression, and posture. IOP is measured by tonometry: indentation tonometry, applanation tonometry, or a noncontact method using an air pulse. These methods may result in slightly different pressure readings. IOPs consistently greater than 21 mm Hg (2.8 kPa) are found in 5% to 8% of the general population. The incidence increases with age, such that "abnormal" (i.e., >22 mm Hg [>2.9 kPa]) IOP is found in 15% of those 70 to 75 years of age. Intermittently high IOP (>40 mm Hg [>5.3 kPa]) is found in patients with closed-angle glaucoma (CAG). The increased IOP in all types of glaucoma results from the decreased facility for aqueous humor outflow through the trabecular meshwork. Aqueous humor production in primary open-angle glaucoma (POAG) is normal.[1,2,17–19]

IOP demonstrates considerable circadian variation (often referred to as *diurnal* IOP or the IOP during the daily 24-hour cycle) primarily because of changes in the rate of aqueous humor formation. This circadian variation results in a minimum IOP at approximately 6 PM and a maximum IOP at awakening, although some studies suggest that both healthy and glaucoma patients may have their highest IOP at night after falling asleep.[20] Low systemic blood pressure in conjunction with high IOPs (decreased ocular perfusion pressure) at night can result in optic nerve head damage.[20] Generally, the circadian IOP variation is usually less than 3 to 4 mm Hg (0.4 to 0.5 kPa); however, it may be greater for patients with glaucoma. This circadian variation and the poor rela-

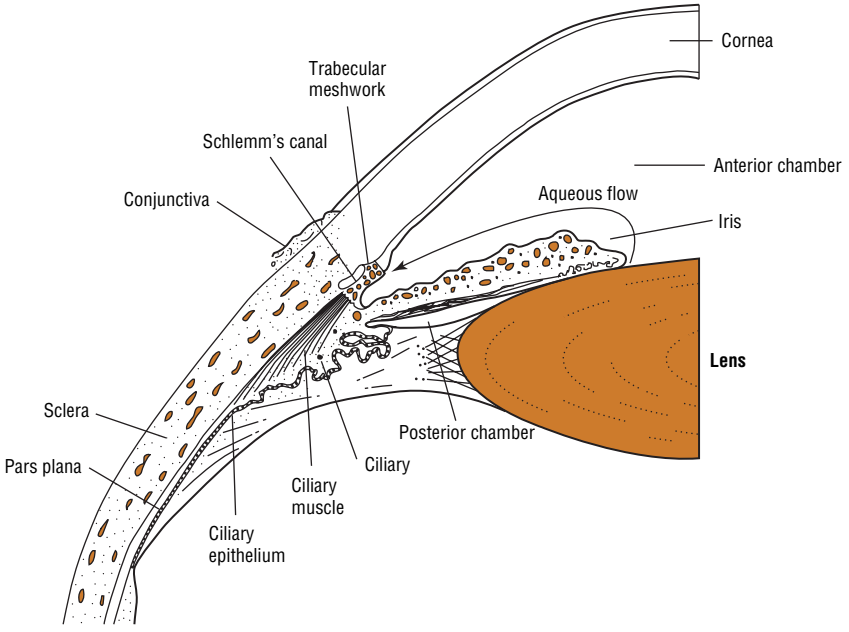

FIGURE 103-2. Anterior chamber of the eye and aqueous humor flow.

tionship of IOP with visual loss make measurement of IOP a poor screening test for glaucoma.

Although increased IOP within any range is associated with a higher risk of glaucomatous damage, it is both an insensitive and nonspecific diagnostic and monitoring tool. Of individuals with IOP between 21 and 30 mm Hg (2.8 and 4.0 kPa), only 0.5% to 1% per year will develop optic disk changes and visual field loss (i.e., glaucoma) over 5 to 15 years. However, more subtle retinal damage, such as alteration of color vision or decreased contrast sensitivity, occurs in a higher percentage of patients with IOPs greater than 21 mm Hg (2.8 kPa), and the incidence of visual field defects increases to as high as 28% in individuals with IOPs above 30 mm Hg (4.0 kPa). For a given abnormal IOP, the incidence of glaucoma increases with age. For patients with preexisting optic nerve damage, the worse the existing damage, the more sensitive the eye is to a given IOP. As many as 20% to 30% of patients with glaucomatous visual field loss have an IOP of less than 21 mm Hg (2.8 kPa) (called *normal-tension glaucoma*, referring to the normal IOP). Thus the absolute IOP is a less-precise predictor of optic nerve damage. More direct measurements of therapeutic outcome, such as optic disk examination and visual field evaluation, also must be used as monitors of disease progression.[1–7,17–24] Taking the above factors into consideration, glaucoma medications that provide maximal reduction of IOP over 24 hours and have minimal influence on blood pressure may be advantageous in treating glaucoma patients.

OPTIC DISK AND VISUAL FIELDS

The optic disk is the portion of the optic nerve ophthalmoscopically visible as it leaves the eye. It consists of approximately 1 million retinal ganglion nerve cell axons, blood vessels, and supporting connective tissue structures (lamina cribrosa). The small depression within the disk is termed the *cup* (Fig. 103–3). A normal physiologic cup does not extend beyond the optic nerve rim and has a varying diameter of less than one third to one half that of the disk (cup-to-disk ratio: 0.33 to 0.5). Table 103–2 lists the common alterations of the optic disk found in glaucoma. These disk changes result from optic nerve axonal degeneration and remodeling of the supporting structures. As the nerve axons die, the cup becomes larger in relation to the whole disk. A loss of retinal nerve fiber layer visibility might be visualized in glaucoma patients with detectable visual field loss. This pattern of changes is consistent with visual field losses and loss of visual sensitivity seen in glaucoma.[1,2,17–24] Damage to the optic nerve can be documented by optic disk photographs, and disease stability or progression may be monitored by examining sequential photographs. Newer methods of assessing damage to the retinal nerve fiber layer and optic disk have been described. These include scanning laser polarimetry (GDX), confocal laser ophthalmoscopy (Heidelberg retinal tomography, or HRT), and optical coherence tomography (OCT). These methods offer the ability to assess the damage to the optic nerve quantitatively.

Determination of the visual field allows assessment of optic nerve damage and is an important monitoring parameter in treatment. However, visual field changes lag behind optic disk changes, and a loss of 25% to 35% of retinal ganglion cells is usually required before detectable visual field defects are noted. The peripheral visual field is measured using a visual field instrument called a *perimeter*. Characteristic visual field loss occurs in glaucoma (Fig. 103–4; see also Table 103–2), but loss of central visual acuity usually does not occur until late in the disease. Other indicators, such as color vision changes and contrast sensitivity, may allow earlier and more sensitive detection of glaucomatous changes.[1,2]

TABLE 103-2 Optic Disk and Visual Field Findings

Optic disk
Cup-to-disk ratio >0.5
Progressive increase in cup size
Cup-to-disk ratio asymmetry >0.2
Vertical elongation of the cup
Excavation of the cup
Increased exposure of lamina cribrosa
Pallor of the cup
Splinter hemorrhages
Cupping to edge of disk
Notching of the cup (usually superior or inferior)
Nerve fiber defects
Visual field findings
General peripheral field constriction
Isolated scotomas (blind spots)
Nasal visual field depression ("nasal step")
Enlargement of blind spot
Large arc-like scotomas
Reduced contrast sensitivity
Reduced peripheral acuity
Altered color vision

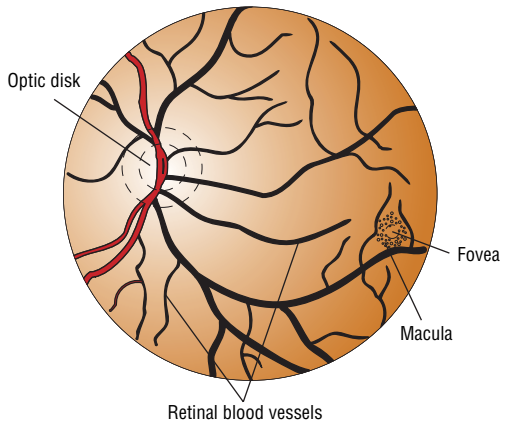

FIGURE 103-3. Normal fundus of the eye and optic disk and cup.

GENETICS

Glaucoma is often inherited as a complex multifactorial disease, but it can also be inherited as a Mendelian autosomal-dominant or autosomal-recessive trait form. The common age-related adult-onset glaucoma, like POAG, although containing heritability of some significance, is more complex and is influenced by environmental factors. Genetic studies have more clearly defined the underlying molecular events responsible for the Mendelian forms of the disease. However, the chromosome locations identified may play some factor in the more complex forms. A number of major gene loci associated with POAG have been identified. The molecular mechanism of how mutations in any of these genes result in increased IOP with loss of visual field has not been elucidated. The future of genetic studies in glaucoma will include discovery of new glaucoma genes, determination of clinical phenotypes associated with these genes and mutations, understanding how environmental factors interact, and developing a database that can be used for further testing. It is hoped that improved understanding of the genetic origins of POAG will lead to new diagnostic tools and therapies that target the underlying causes of the disease.[1,2,25,26]

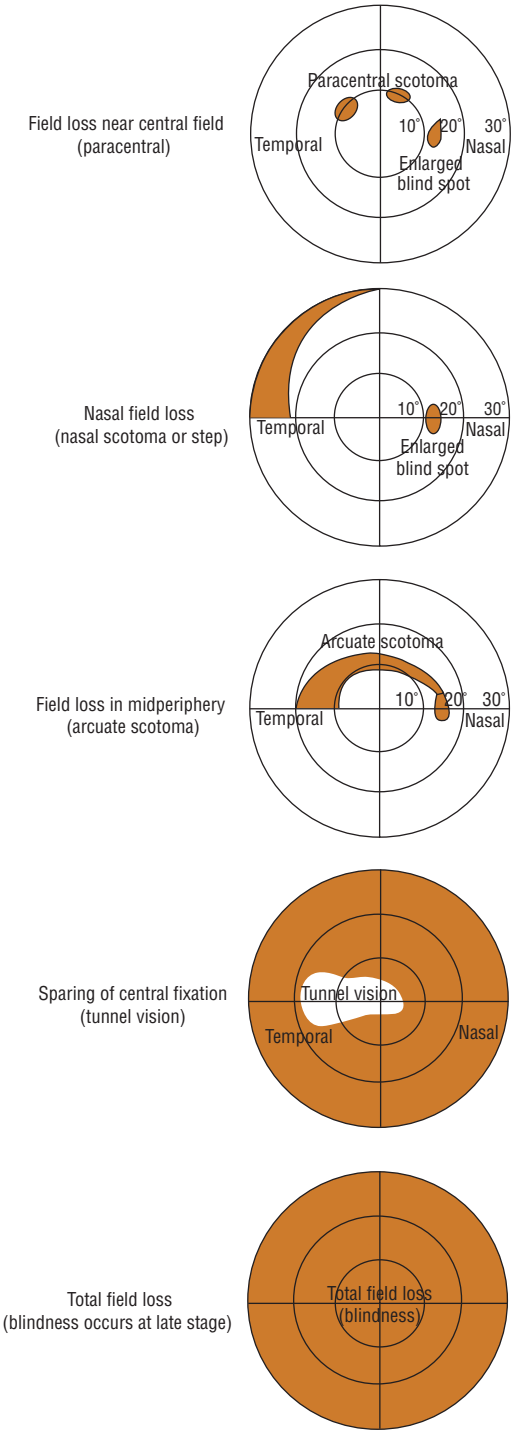

FIGURE 103-4. Schematic of the progression of visual field loss in glaucoma.

EPIDEMIOLOGY OF OPEN-ANGLE GLAUCOMA

1 Open-angle glaucoma (OAG) is the second leading cause of blindness, affecting up to 3 million individuals in the United States and up to 60.5 million individuals worldwide by 2010. It is estimated that by 2010, 135,000 persons in the United States and about 4.5 million in the world will have bilateral blindness. The prevalence rate varies with age, race, diagnostic criteria, and other factors. In the United States, OAG occurs in 1.5% of the population older than 30 years of age, 1.3% of whites and 3.5% of blacks. Recent study data have also suggested that the prevalence of OAG and ocular hypertension is also high among Latinos of Mexican ancestry, with approximately 4.74% and 3.56% of people affected, respectively.[27] The incidence of OAG increases with increasing age. The incidence of the disease for patients 80 years of age is 3% in whites and 5% to 8% in blacks.

ETIOLOGY OF OPEN-ANGLE GLAUCOMA

2 The specific cause of glaucomatous optic neuropathy is presently unknown. Previously, increased IOP was considered to be the sole cause of the damage; however, it is now recognized that IOP is only one of many factors associated with the development and progression of glaucoma.[1–10] Increased susceptibility of the optic nerve to ischemia (a reduced or dysregulated blood flow), excitotoxicity, autoimmune reactions, and other abnormal physiologic processes are likely additional contributory factors. The final outcome of these processes is believed to be apoptosis of the retinal ganglion cells, which results in axonal degeneration and finally permanent loss of vision.[11–16] Interestingly enough, there appears to be a fair amount of similarity between neuronal cell death by apoptosis in Alzheimer disease and glaucoma.[13] Indeed, OAG may represent a number of distinct diseases or conditions that simply manifest the same symptoms. Susceptibility to visual loss at a given IOP varies considerably; some patients do not demonstrate damage at high IOPs, whereas other patients have progressive visual field loss despite an IOP in the normal range (normal-tension glaucoma).

Although IOP poorly predicts which patients will have visual field loss, the risk of visual field loss clearly increases with increasing IOP within any range. In fact, recent studies demonstrate that lowering IOP, no matter what the pretreatment IOP, reduces the risk of glaucomatous progression or may even prevent the onset to early glaucoma in patients with ocular hypertension.[3–7]

The mechanism by which a certain level of IOP increases the susceptibility of a given eye to nerve damage remains controversial. Multiple mechanisms are likely to be operative in a spectrum of combinations to produce the death of retinal ganglion cells and their axons in glaucoma. Pressure-sensitive astrocytes and other cells in the optic disk supportive matrix may produce changes and remodeling of the disk, resulting in axonal death. Vasogenic theories suggest that optic nerve damage results from insufficient blood flow to the retina secondary to the increased perfusion pressure required in the eye, dysregulated perfusion, or vessel wall abnormalities, and results in degeneration of axonal fibers of the retina. Another theory suggests that the IOP may disrupt axoplasmal flow at the optic disk.

Recently, focus on the mechanisms of the retinal ganglion cell apoptosis and the role of excessive glutamate and nitric oxide found in glaucoma patients has broadened the focus of drug therapy research to include evaluation of agents that act as neuroprotectants.[12–15] Such agents may be particularly useful for patients with normal-pressure glaucoma, in whom pressure-independent factors may play a relatively larger role in disease progression. These agents would target risk factors and underlying pathophysiologic mechanisms of disease other than IOP.[11–16]

PATHOPHYSIOLOGY OF OPEN-ANGLE GLAUCOMA

3 As stated previously, optic nerve damage in POAG can occur at a wide range of IOPs, and the rate of progression is highly variable. Patients may exhibit pressures in the 20 to 30 mm Hg (2.7 to 4.0 kPa) range for years before any disease progression is noticed in the optic disk or visual fields. That is why OAG is often referred to as the "sneak thief of sight."

CLINICAL PRESENTATION OF GLAUCOMA

General

- Glaucoma can be detected in otherwise asymptomatic patients, or patients can present with characteristic symptoms, especially vision loss. POAG is a chronic, slowly progressive disease found primarily in patients older than 50 years of age, whereas CAG is more typically associated with symptomatic acute episodes.

Symptoms

- POAG: None until substantial visual field loss occurs.
- CAG: Nonsymptomatic or prodromal symptoms (blurred or hazy vision with halos around lights that is caused by a hazy, edematous cornea, and occasionally headache) may be present. Acute episodes produce symptoms associated with a cloudy, edematous cornea, ocular pain, or discomfort, nausea, vomiting, abdominal pain, and diaphoresis.

Signs

- POAG: Disk changes and visual field loss (see Table 103–2); IOP can be normal or elevated (>21 mm Hg [>2.8 kPa]).
- CAG: Hyperemic conjunctiva, cloudy cornea, shallow anterior chamber, and occasionally an edematous and hyperemic optic disk; IOP is generally elevated markedly (40 to 90 mm Hg [5.3 to 12.0 kPa]) when symptoms are present.

Laboratory Tests

- None

Other Diagnostic Tests

- Emerging tests include OCT, retinal nerve fiber analyzers, and confocal scanning laser tomography of the optic nerve.

CLINICAL PRESENTATION OF OPEN-ANGLE GLAUCOMA

POAG is a bilateral, genetically determined disorder constituting 60% to 70% of all glaucomas and 90% to 95% of primary glaucomas (see Clinical Presentation of Glaucoma above). An increased IOP is not required for diagnosis of POAG. Symptoms do not present until substantial visual field constriction occurs. Central visual acuity typically is maintained, even in the late stages of the disease. Even though POAG is a bilateral disease, it may have greater progression and severity in one eye.

4 Detection and diagnosis involve evaluation of the optic disk and retinal nerve fiber layer, assessment of the visual fields, and measurement of IOP. The presence of characteristic disk changes and visual field loss with or without increased IOP confirms the diagnosis of glaucoma. Typical disk changes and field loss occurring at an IOP of less than 21 mm Hg (2.8 kPa) account for 20% to 30% of patients and are referred to as *normal-tension glaucoma*. Elevated IOP (>21 mm Hg [>2.8 kPa]) without disk changes or visual field loss is observed in 5% to 7% of individuals (known as *glaucoma suspects*) and is referred to as *ocular hypertension*. New technologies such as OCT, retinal nerve fiber analyzers, or confocal scanning laser tomography of the optic nerve head may allow early identification of signs of glaucomatous retinal changes in ocular hypertensives, thus allowing for earlier initiation of therapy.[1–3,17]

Secondary OAG has many causes, including exfoliation syndrome, pigmentary glaucoma, systemic diseases, trauma, surgery, ocular inflammatory diseases, and medications. A system for classifying secondary glaucomas into pretrabecular, trabecular, and posttrabecular forms has been proposed. This classification allows drug therapy to be chosen on the basis of the pathogenic mechanism involved. In pretrabecular forms, a normal meshwork is covered and does not permit aqueous humor outflow. Trabecular forms of secondary glaucoma result from either an alteration of meshwork or an accumulation of material in the intertrabecular spaces. The posttrabecular forms result primarily from disorders causing increased episcleral venous blood pressure.[1,2,15–17]

PROGNOSIS OF OPEN ANGLE GLAUCOMA

5 In most cases of POAG, the overall prognosis is excellent when it is discovered early and treated adequately. Even patients with advanced visual field loss can have continued visual field loss reduced if the IOP is maintained at low enough pressures (often <10 to 12 mm Hg [<1.3 to 1.6 kPa]). Progression of visual field loss still occurs in 8% to 20% of patients despite reaching standard therapy IOP goals. However, for untreated patients and for those who fail to achieve target IOP reduction, up to 80% have continued visual field loss. Estimates of progression to bilateral blindness in treated patients range from 4% to 22%. Thus, the keys to medical treatment of POAG are an effective, well-tolerated drug regimen, close monitoring of therapy, and adherence. Medications will control IOP successfully in 60% to 80% of patients over a 5-year period. Availability of newer, highly effective, well-tolerated agents may improve the prognosis further.[1,2,5,17–19,23–28]

EPIDEMIOLOGY OF CLOSED-ANGLE GLAUCOMA

The incidence of CAG varies by ethnic group, with a higher incidence in individuals of Inuit, Chinese, and Asian-Indian descent. Incidence rates of 1% to 4% have been reported in these populations.[1,2]

ETIOLOGY OF CLOSED-ANGLE GLAUCOMA (ANGLE-CLOSURE GLAUCOMA)

Primary CAG accounts for 5% or less of primary glaucomas; however, when CAG occurs, it may need to be treated as an emergency to avoid visual loss. CAG results from mechanical blockage of the (usually normal) trabecular meshwork by the peripheral iris. Partial or complete blockage of the meshwork occurs intermittently, resulting in extreme fluctuations between normal IOP with no symptoms and very high IOP with symptoms of acute CAG. Between attacks of CAG, the IOP is usually normal unless the patient has concomitant OAG or nonreversible blockage of the meshwork with synechiae ("creeping" angle closure) that develops over time in the narrow-angle eye. Primary CAG occurs for patients with inherited shallow anterior chambers, which produce a narrow angle between the cornea and iris or tight contact between the iris and lens (pupillary block). The presence of a narrow angle is determined mainly by visualization of the angle by gonioscopy. Other tests for CAG involve provocation of an angle-closure–induced IOP increase. These tests, which attempt to produce angle closure through mydriasis (darkroom test or mydriasis test) or gravity (prone test), are rarely performed in the clinical setting.

Two major types of classic, reversible primary CAG have been described: CAG with pupillary block and CAG without pupillary block. CAG with pupillary block results when the iris is in firm contact with the lens. This produces a relative block of aqueous flow through the pupil to the anterior chamber (pupillary block), resulting in a bowing forward of the iris, which blocks the trabecular meshwork. CAG with pupillary block occurs most commonly when the pupil is in middilation. In this position, the combination of pupillary block and relaxed iris allows the greatest bowing of the iris; however, angle closure may occur during miosis or mydriasis.

CAG can occur without significant pupillary block for patients with an abnormality called a *plateau iris*. The ciliary processes in

these cases are situated anteriorly, which indent the iris forward and cause closure of the trabecular meshwork, especially during mydriasis. The mydriasis produced by anticholinergic drugs or any other drug results in precipitation of both types of CAG glaucoma, whereas drug-induced miosis may produce pupillary block.

PATHOPHYSIOLOGY OF CLOSED-ANGLE GLAUCOMA

The mechanism of IOP elevation in CAG is clearer than that of POAG. In CAG, a physical blockage of trabecular meshwork is present. In many cases, single or multiple episodes of excessively high IOP (>40 mm Hg [>5.3 kPa]) result in optic nerve damage. Very high IOP (>60 mm Hg [>8.0 kPa]) may result in permanent loss of visual field within a matter of hours to days.

One type of CAG, known as "creeping" angle closure, occurs in patients with narrow angles in which the iris adheres to the trabecular meshwork and may result in continuously increased IOP in ranges more similar to those of POAG, and the clinical behavior is similar to POAG, with individuals differing in the degree and rapidity of visual loss from any given elevated IOP.[1]

CLINICAL PRESENTATION OF CLOSED-ANGLE GLAUCOMA

Patients with untreated CAG typically experience intermittent nonsymptomatic or prodromal symptoms brought on by precipitating events (see Clinical Presentation of Glaucoma above). Increased IOP during such prodromal episodes is not great enough or long enough to produce the other symptoms of a full-blown attack. Such prodromal attacks last 1 to 2 hours, at which time pupillary block is broken by further mydriasis or miosis, or when miosis or mydriasis occurs in patients with plateau iris. The rate at which IOP increases may be a determinant of when full-blown symptoms occur. Visual fields demonstrate generalized constriction or typical glaucomatous defects. In prolonged attacks, total loss of vision may occur if the IOP is high enough. Tonometry reveals IOPs as high as 40 to 90 mm Hg (5.3 to 12.0 kPa). Patients who have developed adhesions between the iris and meshwork (anterior synechiae) may have chronic IOP elevation with intermittent spikes of high IOP when angle closure occurs.

DRUG-INDUCED GLAUCOMA

A number of medications are associated with increased IOP or carry labeling that cautions against use of the medication in glaucoma patients. The potential for a medication to produce or worsen glaucoma depends on the type of glaucoma and whether the patient is treated adequately.[25]

Patients with treated, controlled POAG are at minimal risk of induction of an increase in IOP by systemic medications with anticholinergic properties or vasodilators; however, for patients with untreated glaucoma or uncontrolled POAG, the potential of these medications to increase IOP should be considered. Topical anticholinergic agents used to produce mydriasis may result in an increase in IOP. Potent anticholinergic agents such as atropine or homatropine are most likely to increase IOP. Weaker anticholinergics, such as tropicamide, that produce less cycloplegia are less likely to increase IOP and are favored, along with phenylephrine, when mydriasis is desired for POAG patients. Inhaled, nasal, topical, or systemic glucocorticoids may increase IOP for both normal individuals and patients with POAG.

Patients with POAG appear to be particularly susceptible to glucocorticoid-induced increases in IOP. Glucocorticoids reduce the facility of aqueous humor outflow through the trabecular meshwork. The decreased facility of outflow appears to result from the accumulation of extracellular material blocking the trabecular channels. The potential of a glucocorticoid to increase IOP is related to its antiinflammatory potency and intraocular penetration. Thus, patients should be treated with the lowest potency and dose and for the shortest time possible when steroids are indicated.

TABLE 103-3 Drugs that may Induce or Potentiate Increased Intraocular Pressure

Open-angle glaucoma
Ophthalmic corticosteroids (high risk)
Systemic corticosteroids
Nasal/inhaled corticosteroids
Fenoldopam
Ophthalmic anticholinergics
Succinylcholine
Vasodilators (low risk)
Cimetidine (low risk)
Closed-angle glaucoma
Topical anticholinergics
Topical sympathomimetics
Systemic anticholinergics
Heterocyclic antidepressants
Low-potency phenothiazines
Antihistamines
Ipratropium
Benzodiazepines (low risk)
Theophylline (low risk)
Vasodilators (low risk)
Systemic sympathomimetics (low risk)
Central nervous system stimulants (low risk)
Serotonin selective reuptake inhibitors
Imipramine
Venlafaxine
Topiramate
Tetracyclines (low risk)
Carbonic anhydrase inhibitors (low risk)
Monoamine oxidase inhibitors (low risk)
Topical cholinergics (low risk)

For patients predisposed to CAG (i.e., narrow anterior chambers), angle closure may be produced by any drug that causes mydriasis (e.g., anticholinergics). A wide range of sulfa compounds causes idiosyncratic reactions that result in anterior choroidal effusions with anterior movement of the iris and lens, resulting in angle closure. The topical use of anticholinergics or sympathomimetic agents most likely will result in angle closure. Systemic and inhaled anticholinergic and sympathomimetic agents also must be used with caution in such patients. As discussed previously, potent miotic agents such as echothiophate may produce angle closure by increasing pupillary block. Table 103–3 lists the drugs associated with potentiation of glaucoma.

TREATMENT

Ocular Hypertension
